bove 12 groups, just a half returned a higher daily sick-rate than the ratio ble European Army, the highest being 105 per 1,000 of average strength in ic Plain and Chutia-Nagpur, South-Eastern Rajputana, &c., and Hill t Depôts groups. The Burma Inland group followed with a ratio of 102 and nd Orissa and Deccan groups came next with ratios of 97 per 1,000 each. est ratio (72) was returned by the Southern India group. The death-rate of the rmy was exceeded by three groups, viz., the Indus Valley and North-Western na, Bengal and Orissa and Gangetic Plain and Chutia-Nagpur groups.
e stations with a strength of over 1,000, four returned death-rates above 20 per iz., Peshawar 32·99, Lucknow 21·51, Chakrata 20·59, and Aden 20·23.

ortality from cholera in the European Army was very low. The admissions tal from the disease numbered only 44 or 0·6 per 1,000 of average strength, 209 or 2·9 per 1,000 in 1894, and the deaths fell from 149 or 2·10 per 1,000, 0·45.

g the whole of the European troops in India there were during the year under ly 19 cases of small-pox; of these two were fatal, one each in the Bengal ras Commands. In the previous year there were 13 cases and three deaths.

intermittent fever the admissions to hospital among the European troops in re in the ratio of 336 per 1,000 of strength against 412 in the previous year hs under this head numbered 18, an increase of 5 on the mortality of 1894. 8 occurred among troops in the Punjab Command and 5 among those in the Command.
enteric fever the admissions rose from 1,484 or 20·9 per 1,000 of strength, to 26·3, and the deaths from 409 or 5·75 per 1,000 to 477 or 6·72. Of the four ds Punjab recorded the highest mortality under this head, viz., 10·29, by Bengal with a ratio of 7·59, Bombay 4·48, and Madras 2·61. Among the ations with an average strength of over 1,000, Peshawur returned a death- this fever of 16·80, Chakrata 15·69, Lucknow 15·36, Agra 14·75, Meerut in two other stations (Umballa and Rawalpindi) the ratios exceeded that for army. As usual, young and unacclimatised soldiers were the chief sufferers; ose under 25 years of age the death-rate was 8·22 per 1,000 against 8·51 in ile among men between 25 and 29, and from 30 to 34, the mortality was 2·89 per 1,000 respectively. Among men of less than one year's residence in death-rate from this fever was 10·83 per 1,000, among men between one years 3·30, and among troops between five and ten years' service the rate per 1,000.

nissions from dysentery and diarrhœa among the European troops were in f 69 per 1,000 of strength or 12 per 1,000 more than in 1894. The mortality ntery was in the ratio of 1·04, and from diarrhœa 0·07 per 1,000. Dysentery ea were most prevalent in the Punjab Command.

REPORT.

The present Report on Sanitary Measures in India during the year 1895 is prep for presentation to Parliament. It contains chapters on the health of the Euro and Native troops, on the health of prisoners in jails, and on the health of the gen population; it also contains chapters on vaccination, on medical institutions, inclu medical schools and lunatic asylums, and a chapter on sanitary works. Ap to the Report are abstracts of reports by the three principal Sanitary Commis in India, and memoranda by the Army Sanitary Commission in England re the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

The health of the European troops on service in India during 1895 wa better than in the previous year. On an average strength of 71,031, the admi into hospital were in the ratio of 1,462 per 1,000 against 1,508 in 1894, the sick-rate was 94 or 2 per 1,000 more, and the death-rate fell from 16·07 to 15·26. invaliding ratio (23) was also lower by 2 per 1,000, so that the total loss by deat invaliding was equal to 39 per 1,000, a decrease of 3 per 1,000 on the previous

The Presidential Army system was abolished in 1894, and all the forces in are now designated the Army of India, divided into the Bengal, Punjab, M and Bombay Commands. This organization took effect from the 1st April 1895

The following statement shows the relative extent of sickness and mortality European troops in the four Commands during 1895 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	T
Bengal (including the Punjab in 1894)	1895	22,259	1,436	98	16·98	26	
	1894	44,267	1,567	94	18·55	24	
Punjab	1895	19,733	1,519	92	20·02	18	
Madras	1895	13,417	1,227	91	8·79	31	
	1894	13,397	1,273	89	9·48	29	
Bombay	1895	15,622	1,627	92	12·35	21	
	1894	13,418	1,549	85	14·46	27	
INDIA	1895	71,031	1,462	94	15·26	23	
	1894	71,082	1,508	92	16·07	25	

It will be seen from the above statement that of the four Commands Beng highest daily sick-rate and the Punjab the highest death-rate. The Madras C was the healthiest, and its death-rate was less than half that of the Punjab.

The chief causes of sickness in the whole European Army were, as in the y venereal diseases and ague, the former yielding a ratio of 522 per 1,000 ag in 1894, and the later 336 per 1,000 against 412. More than half (59 per the total sickness resulted from these two causes. Enteric fever, as usual chief cause of mortality, and the death-rate from it was 6·72 per 1,000 ag in 1894. This fever caused 44 per cent. of the total deaths.

Venereal diseases as usual came first in the list of causes of admission to hospital; and also in the causes of invaliding. They were the cause of 36 per cent. of the total sickness during 1895, and nearly 20 per cent. of the invaliding of the European Army of India. The ratio of admissions from venereal diseases per 1,000 of strength was 522 or 11 above that of 1894. This is vastly in excess of the ratio of most continental armies, and also of the ratios of British troops in other parts of the world. The admission-rate under this head was highest in the Bengal Command, viz., 605 per 1,000, next came Madras with a ratio of 531, Bombay with 527, and the Punjab 419. Dr. Cleghorn, Sanitary Commissioner with the Government of India, in his report for the year under notice, gives figures "showing clearly how the "arrival year by year of fresh batches of young unmarried men under the short "service system has been accompanied by an increase of venereal disease. Since 1878 "the number of fresh troops arriving in the country has, as a rule, been much greater "than before. The gradual rise in the percentage of men under 25 years of age in "the army, and of men under five years' Indian service has been pretty uniform, as "has been the well-marked decline in the number of married men; and the same "may be said of the gradual rise in the venereal ratio. As youth and recent arrivals "have become more common in the army, venereal disease and enteric fever have not "unnaturally increased in frequency of occurrence." . . . . Statistics also "show a more or less continuous rise in the incidence of venereal disease, more "especially since 1885; and the increase in the ratio of secondary syphilis is of grave "importance, more particularly with regard to the individual. No man who has not "been effectually cured of syphilis can be reckoned upon as an efficient soldier; and "the mischief is not confined to the individual, as the physical weaknesses are "continued to succeeding generations." The Army Sanitary Commission remark "that the great and increasing prevalence of this class of disease in India is most "lamentable, and we are glad to learn that an earnest attempt is being made on the "part of the Indian Government to devise some measures for dealing with it. The "evil has reached dimensions which threaten to be ruinous to the efficiency of the "European Army in India, to say nothing of its far-reaching and dreadful effects on "a number of innocent persons in this country."

The loss to the whole army by invaliding during 1895 amounted to 1,663 men, equal to 23·4 per 1,000, against 1,808 or 25·4 in 1894. The proportion of invalids to strength was highest in the Madras Command (31·2), followed by Bengal (25·5), Bombay (20·7), and Punjab (17·9). Of the total number invalided, 33 per cent. were discharged as unfit for further service, being 6 per 1,000 lower than in 1894. As regards the influence of age and length of residence in India upon invaliding, 66 per cent. of the total number invalided were under 25 years of age, against 60 in 1894, while 36 per cent. were of less than two years' service, and 86 per cent. were of less than five years' service. In the European Army as a whole 83 per cent. of the total strength had seen less than five years' service.

II.—NATIVE ARMY.

There was less sickness in the Native Army of India during 1895 than in the previous year, but the mortality was slightly higher, which was due to the greater prevalence of pneumonia, as from all the other chief diseases there was a decrease in the death-rates.

The ratios of sickness and mortality among Native troops in the six Commands during 1895 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal (including the Punjab in 1894)	1895	24,454	790	30	8·26
	1894	65,446	934	33	12·01
Punjab	1895	41,062	878	33	17·58
Madras	1895	26,738	660	30	8·38
	1894	26,628	678	30	9·84
Bombay	1895	25,259	889	28	11·12
	1894	23,757	1,168	34	10·73
Corps of Central India and Rajputana	1895	5,172	595	21	6·77
	1894	5,089	683	20	7·07
Hyderabad Contingent	1895	6,968	617	22	5·74
	1894	6,924	620	21	5·34
India	1895	129,655	794	30	11·60
	1894	127,844	897	31	10·76

Of the six Commands the Punjab was the most unhealthy, due to service in the Waziristan and Chitral expeditions. Pneumonia was very prevalent in this force, and the death-rate from it was 8·33 per 1,000 or nearly half of the total mortality.

The chief cause of sickness in the Native Army was ague, which caused 36 per cent. of the total admissions against 42 per cent. in the year 1894. Among the diseases from which the admissions to hospital were higher than in 1894 were pneumonia, tubercle of the lungs, dysentery, diarrhœa, and scurvy; while from cholera, ague, simple continual fever, respiratory diseases other than pneumonia, and venereal diseases, there was a decrease in the admissions. From venereal diseases the admission-rate in the Native Army was only 31·3 per 1,000 of strength as compared with 522 per 1,000 among European troops. Figures under this head are not available for the years before 1877. The ratios run at a much lower level than those of European troops, and there is not the same tendency to increase. Only once since 1877 has the rate reached 40 per 1,000, that was in 1890 when the admission-rate was 41·1.

Respiratory diseases were the chief causes of death in the Native Army, and no less than 42 per cent. of the total deaths were due to them. The death-rate under this head was 4·87 per 1,000 of average strength, against 4·20 in 1894. From pneumonia the mortality among the Native soldiers (4·20 per 1,000) was about eight times as great as that among European troops (0·51 per 1,000). Fevers of all kinds were the cause of 16 per cent. of the total deaths, against 48 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 1·81 per 1,000, while among the European troops the proportion was 0·59. On the other hand, the death-rate from enteric fever among Native troops was only 0·07 per 1,000 as compared with 6·72 among the European troops. From cholera there were only 53 deaths in the Native Army, equal to 0·41 per 1,000 of strength, as compared with 71 and 0·56 respectively in 1894.

The following statement gives the principal statistics of the Native Army in geographical groups for 1895 :—

	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Dea
Burma Coast and Bay Islands -	2,145	545	24	12·
Burma, Inland - - -	6,680	978	43	10·
Assam - - - -	2,259	1,037	39	14·
Bengal and Orissa - - -	3,047	982	37	5·
Gangetic Plain and Chutia-Nagpur -	6,493	598	23	7·2
Upper Sub-Himalayan - -	12,613	738	30	11·6
Indus Valley and North-Western Rajputana - - - -	14,749	994	35	18·71
South-Eastern Rajputana, Central India, and Gujarat - - -	13,052	715	24	7·59
Deccan - - - -	20,686	764	27	6·62
Western Coast - - -	3,096	653	30	9·69
Southern India - - -	9,092	574	26	6·93
Hill Stations - - -	15,081	971	37	13·53

In five of the above groups the daily sick and death-rates were higher th those for the whole Native Army. The highest mortality was that of the Ind Valley and North-Western Rajputana group (18·71), which shows an increase 4·87 per 1,000 on the rate for the previous year.

Of the stations with a strength of over 1,000, the following recorded death-ra exceeding 20 per 1,000 of strength :—Edwardesabad (36·06), Dera Ghazi Khan (23·1 Kohat (22·67), Dharmsala (20·97), and Dehra Dun (20·78).

III.—GENERAL POPULATION.

s were registered throughout all the 10 provinces of India in 1895, and the tes varied between 43·91 and 26·39 per 1,000 of population under registration. st results were obtained in the Punjab, Berar, Bombay, the North-Western ces and Oudh, Bengal and the Central Provinces, their respective rates being 7·2, 35·8, 34·9, 34·6, and 33·4. In the remaining provinces the birth-rates between 31·0 in Assam and 26·39 in Coorg. In five provinces the birth-rates igher than in the previous year, and in four they were lower. The birth- xceeded the death-rates in seven provinces, the excess per 1,000 varying between n the Punjab and 3·20 in Bengal. The year 1895 was more healthy than the ding year, and the recorded deaths fell from 7,241,323 or 33·08 per 1,000 of tered population in 1894, to 6,163,743 or 28·94. With the exception of Assam, r, and Coorg, the number of deaths recorded in the several provinces was lower in 1894. Of the chief diseases, cholera was much less prevalent, and the total ber of deaths from it fell from 521,647 to 310,797. The decrease was spread over of the provinces, the others showed a material increase. There was a considerable rease also in the deaths from fevers, which was participated in by all the provinces pt Assam, Madras, and Coorg. In connexion with this cause of death the scheme the sale of quinine at a low price by postal agency was making steady progress. he mortality from dysentery and diarrhœa was also lower than in the previous year; t from small-pox there was an increase of 2,719 deaths.

The deaths from the chief diseases and from all causes in the several provinces were follow :—

	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Deaths from all Causes.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000 of Population under registration.

The public health in Bengal during 1895 was generally better than in the previous year, which was one of the most unhealthy known. The birth-rate was higher, though still considerably below the ratio estimated by actuaries. The number of births registered in the province rose from 2,332,247 or 32·81 per 1,000 of population in 1894 to 2,458,623 or 34·59 per 1,000, the latter being made up of district rates varying from 46·61 in Noakhali and 45·92 in Backergunge to 25·73 in 24 Parganas. Of the 46 districts there was an increase of births in 33, the greatest advance being in Noakhali, where the ratio was 8·93 per 1,000 in excess of the previous year. Manbhum came next with an increase of 7·02, followed by Tippera with an increase of 6·90, and then Midnapore, Mymensingh, and Rajshahi, each with an improvement of over 5 per 1,000. In rural areas the birth-rate was 35·13 per 1,000, and in towns 23·91, as compared with 33·32 and 22·71 respectively in 1894. Out of 147 towns only four returned a birth-rate in excess of 40 per 1,000, while 42 rural areas returned rates of 45 per 1,000 and over.

The total number of deaths registered during the year under notice was 2,231,458, or 31·39 per 1,000 as compared with 2,479,096 or 34·88 in 1894. There was thus an excess of births over deaths of 227,165 or 3·20 per 1,000. The district death-rates ranged from 41·48 in Jessore to 19·62 in Singhbum. In urban areas the rate of

Mortality declined from 35·34 to 34·40, which was made up of ratios varying from 9·44 in the small municipality of Bhadreswar in Hooghly to 12·68 in Jhalakati in Backergunje. Sixteen out of the 147 towns returned a death-rate in excess of 44·8 per 1,000, the estimated normal rate of the province, while 27 returned rates below 25 per 1,000. "In these places" the Sanitary Commissioner (Dr. Dyson) states, "registration seems to be very carelessly carried out. In the towns which returned a "death-rate in excess of the estimated normal the mortality in no less than 11 was in "excess of the previous year. For this cholera in some places and fever in others were "principally responsible." In rural areas the death-rate fell from 34·85 to 31·24, the highest mortality for such areas being recorded in the districts of Jessore (41·52), Nadia (38·85), Darjeeling (38·41), Pabna (37·78), Rajshahi (37·71), Hooghly (37·15), Jalpaiguri (36·08), Dinajpur (35·95), and Faridpur (35·27), but in all of these the figures are considerably below the estimated normal death-rate.

Of the chief death causes cholera was less prevalent in 1895 than in the previous year, the number of deaths registered from it being 177,087 or 2·49 per 1,000 against 236,150 or 3·32 in 1894. Every district was affected by the disease, but the mortality varied greatly, and the number of villages attacked was 24,103 or 10·72 per cent. of the total, against 30,223 or 13·44 per cent. in 1894. Four districts recorded cholera death-rates of over 5 per 1,000, viz., Dacca (7·08), Faridpur (6·03), Nadia (5·36), and Jessore (5·35), and in ten districts the rates were below 1 per 1,000. Nearly all the districts which had the highest cholera mortality in 1894 showed comparatively low rates in 1895. As regards the seasonal incidence of the disease in each of the main geographical divisions of the province, the seasons of highest mortality in Bengal proper were December, April, November, May and March. In Behar the rates were highest in August, June, July, September, and May; in Orissa in November, October, July, September, and August and December equal; in Chota Nagpur in April, May, August, and June. "There can be little doubt," the Sanitary Commissioner says, "that the character of the soil plays an important part in the seasonal "incidence of cholera." Since the close of 1895, Dr. Haffkine, with a special staff, has been engaged under the Bengal Sanitation Department, in cholera inoculation. A large number of people were inoculated in the areas in which cholera has lately been prevailing in epidemic form, especially Serampore, but a complete statement of the results has not yet been furnished, owing to Dr. Haffkine's absence in Bombay on an inquiry into the nature of the plague.

From small-pox the mortality was higher than in 1894, the number of deaths having risen from 8,404 or 0·11 per 1,000 to 13,020 or 0·18 in 1895, an insignificant rate, however, when compared with those from other diseases prevalent in Bengal. The disease was present in all the districts except Singhbhum, but excluding Calcutta, where there was a severe epidemic, the death-rate reaching 3·25, in no other district did the ratio reach 1 per 1,000. Faridpur district returned the next highest rate (0·72). This district is notorious for its opposition to vaccination, headed by the influential sect of Ferazi Muhammadans. At the close of the year steps were taken to overcome the opposition with satisfactory results, the Ferazi High Priest, Maulvi Syuddin, and through his influence all the most important leaders of religious and other communities almost throughout Eastern Bengal, being now believers in vaccination.

No less than 73 per cent. of the total deaths were recorded under fever, a term which, Dr. Dyson observes, is loosely construed by the illiterate agency responsible for reporting deaths, so that pneumonia, phthisis, and other diseases attended with a rise of temperature, and practically nearly all diseases except small-pox and cholera, are included under this heading. The number of deaths reported to have occurred from fever during the year was 1,634,254 or 22·99 per 1,000 of population, against 1,799,833 or 25·32 in 1894. Just a half of the 46 districts recorded a higher fever mortality than the provincial rate, seven registering a rate over 30 per 1,000. With only one exception (Hooghly) the soil of the districts with highest fever mortality is alluvial, "and the natural drainage has been more or less obstructed by "changes of level and the shifting of the courses of the rivers." At the same time Dr. Dyson points out that malarial fever is by no means confined to alluvial areas with defective drainage. "The malarial parasite," he says, "seems to be in evidence all over "the province, and requires but certain modifications of heat, moisture, and organic "matter present to excite it to active propagation, one of the chief factors which "influence this being moisture as determined by rainfall and subsoil water "fluctuation."

From dysentery and diarrhœa 49,871 deaths were registered, equal to 0·70 per 1,000 of population, against 58,812 or 0·82 in the previous year. Of the districts, Calcutta

returned the highest death-rate from these causes (4·79), Howrah came next (4·65), followed by Darjeeling (3·90), Balasore (3·21), and Puri (3·20). These five districts have headed the list, though in a different order, for the last three years.

In Calcutta the birth-rate was only 16·0 per 1,000, the lowest on record since 1889, while the death-rate (39·6) was the highest. The increase in the number of deaths, from 22,441 in 1894 to 27,031 in 1895, is reported to be due to fevers and small-pox, those from the former having risen from 8,963 to 11,345, and those from the latter from 405 to 2,220. Cholera also was more prevalent than in the previous year, and the deaths from it rose from 1,695 to 2,090. Professor Haffkine's method of inoculation as a prophylactic against the disease was carried on during the year and 2,038 operations were performed. Dr. Simpson, the Health Officer of the city, examined the evidence as to the efficacy of this process, and expressed his opinion that "by precise observations "it has been proved that the anti-choleraic inoculations reduce the mortality in the "first four days by an average of 3·24 times, and that the people inoculated after this "period acquire a protection which for a year at least renders them 22·62 times safer "than the uninoculated." Of the 2,220 deaths from small-pox about a third (708) occurred among children under five years of age who had not been protected by vaccination, inoculation, or a previous attack of the disease; while on the other hand there was not a single death from it amongst vaccinated children of that age. This contrast, the Army Sanitary Commission point out, "places the prophylactic value of "vaccination in the strongest light."

North-Western Provinces and Oudh.

The year 1895 in the North-Western Provinces and Oudh was exceptionally healthy. The birth-rate, however, was low, viz., 34·90 per 1,000 of population, as compared with 39·70 in the previous year, and a decennial mean of 39·50. The diminution was attributed to the extreme unhealthiness of the year 1894, the mortality returns of which, the officiating Sanitary Commissioner, Dr. Thomson, observes "are in themselves sufficiently indicative of the great amount of fatal disease, but they "only partially show the extent of sickness, and consequent vital depression, existing." The number of births registered during 1895 was 1,637,235, against 1,862,025 in the previous year. The births, however, exceeded the deaths by 270,792, or 5·77 per 1,000. An examination of the district ratios shows that, as in the previous year, Bulandshahr headed the list with a birth-rate of 55·43, Aligarh, Etah, and Agra followed with ratios of 52·36, 51·29, and 51·04 respectively. Out of the 48 districts, 24 recorded birth-rates above the average for the provinces. The town birth-rate was 39·80, and that for rural areas 34·29. Among the former there were great deviations from the average, the extremes, excluding hill stations and Brindaban, where the circumstances are peculiar, ranging from 64·27 in Fatehpur Sikri, to 24·83 in Saharanpur.

The number of deaths registered was 1,366,443 or 29·13 per 1,000 of population, being 627,335 or 13·38 less than in 1894. The highest district death-rate was that of Kheri 44·54, Naina Tal (which includes the Terai) followed with 43·57, and next in order came Hamirpur 40·89, and Saharanpur 40·79; the lowest rates were recorded by Partabgarh, Allahabad, Mainpuri, and Ballia, these ranging from 21·97 to 20·71. Eleven districts showed an excess of deaths over births, against 20 in the previous year. The town death-rate was 33·46, and the rural death-rate was 28·58, as compared with 47·67 and 41·85 respectively in 1894, the former being made up of ratios varying between 75·64 per 1,000 in Deoband and 17·28 in Bareilly. Though still capable of improvement, registration of vital statistics in these provinces is considered to be, on the whole, extremely efficient. An examination of registers by local authorities disclosed an omission of 2·78 per cent. on 21 per cent. of the births and 2·64 on 20 per cent. of the deaths, while, of 241,988 cases tested by the Vaccination Department, the omitted percentages were 1·46 of births and 0·72 of deaths.

The history of the chief diseases shows that the mortality from cholera declined from 178,079 or 3·80 per 1,000 in 1894 to 51,562 or 1·10. The disease prevailed in an epidemic form in the Fyzabad and adjoining districts in the early part of the year and in Hamirpur in the rains. Hamirpur headed the districts with a cholera death-rate of 7·56, followed by Fyzabad 5·51, Basti 4·3, Sultanpur 4·21, Gonda 2·85, Rae Bareli 2·53, Azamgarh 2·42, and Shahjahanpur 2·08. In five other districts the rates varied between 1·72 and 1·11, while the Kumaun division, comprising the districts of Almora, Garhwal, and Naini Tal, were absolutely free from the disease, as were also the Hardwar and Magh Mela fairs. Of the larger towns Fyzabad and Shahjahanpur were the only ones which recorded high cholera death-rates, viz. 5·83 and 3·75 respectively.

The continuous diminution of small-pox in these provinces, which has become more and more pronounced during the past 26 years, was further shown by a reduction in the death-rate from ·09 in 1894, hitherto the lowest rate recorded, to ·04 in 1895, in which year there were 1,968 deaths. The highest district rates were 0·37 in Pilibhit, 0·30 in Kheri, and 0·27 in Jhansi. No deaths from small-pox were recorded in Bijnor district, and in 16 other districts the number of fatal cases was below 10. Out of 100 principal towns in the provinces small-pox was present only in 27, and of these Cawnpore recorded the highest ratio of 0·35.

Comparatively speaking, the mortality from fever was not great. The number of deaths registered under this head in 1895 was 1,093,212 or 23·31 per 1,000 against 1,495,372 or 31·88 in the previous year. The percentage of deaths to total mortality was 80, but little reliance can be placed in this figure as so many diseases are registered under fever. Dr. Thomson observes that many of the deaths were no doubt due to influenza, which was prevalent during the year in several districts. Among the districts Kheri came first with a fever death-rate of 41·99, closely followed by Naini Tal with 40·06; Saharanpur and Pilibhit come next with ratios of 39·23 and 35·24 respectively. Of the larger towns, Muzaffarnagar was the only one showing an exceptional fever mortality, viz., 43·87.

There were 42,778 deaths recorded under dysentery and diarrhœa, being equal to 0·91 per 1,000, as compared with 66,173 or 1·41 in 1894. As usual the death-rates were highest in the hill tracts, Garhwal showing 9·73, Almora 4·83, Dehra Dun 4·88, and Naini Tal 2·10. In the plains the highest rates were Jhansi 3·12, Rae Bareli 2·85, and Bareilly 2·36. The town death-rate from these causes was 2·35, as compared with 0·80 in rural areas. Kashipur, a town in the Terai, again recorded the highest mortality (12·84) under this head.

The year 1895 in the Punjab was a healthy one; the meteorological conditions were more favourable to health, the weather was mild, the rainfall was below the average, and there was no unusual prevalence of epidemic disease. The number of births registered during the year was 901,584 or 43·86 per 1,000 of population, against 902,941 or 43·93 in 1894. The district birth-rates ranged from 54·4 to 37·2. In five districts the birth-rate exceeded 50 per 1,000, viz., Gujranwala 54·4, Jhang 51·9, Gurgaon 51·7, Rohtak 50·9, and Ferozepore 50·7. The comparatively low rates of Amritsar 42·7, Gurdaspur 39·7, Jullundar 39·1, Umballa 38·7, and Hoshiarpur, 37·2, the Sanitary Commissioner, Dr. Roe, attributes to the unhealthiness of these districts in the previous year. The registration of births in the frontier districts continued to improve, especially in Kohat and Bannu, where the averages for the five years ending 1893 of 25·9 and 27·2 respectively, rose in 1894 to 40·4 and 39·6, and in 1895 to 42·0 and 44·2. In rural circles the average birth-rate was 44·3 per 1,000, as compared with 40·0 in the towns. Among the latter, seven returned rates of over 50 per 1,000. Pun

The number of deaths registered in the province in 1895 was 601,972, equal to a death-rate of 29·29 per 1,000 of population, against 750,681 or 36·52 in the preceding year. With four exceptions the mortality of 1895 was the lowest recorded during the previous ten years, and the rate was only 1·16 per 1,000 in excess of that recorded in 1893 (28·13) which was a very healthy year. Simla and Umballa were the only districts in which the deaths exceeded the births. In 12 districts out of 27 the provincial death-rate was exceeded, and in these the rates varied from 42·55 in Umballa to 29·86 in Kohat. In rural circles the average death-rate was 28·8 per 1,000, as compared with 33·7 in the towns. Among the larger towns, Jagadhri returned the highest rate of 50·12 per 1,000, and in eight more the rates varied between 43 and 40 per 1,000.

There was again very little cholera in the province during the year, the deaths from the disease numbering only 549. Of these, 511 occurred in the Umballa district, 31 in Karnal, 4 in Peshawar, and single deaths only in Delhi, Jhang, and Rawalpindi districts. The mortality, however, was in excess of the previous year by 436, there having been but 113 cholera deaths recorded in 1894. It is worthy of notice that within the last 29 years the cholera death-rate in this province has only three times exceeded one per 1,000.

The mortality from small-pox was higher than in 1894, the deaths having risen from 6,068 or 0·30 per 1,000 in that year to 8,334 or 0·41 in 1895, being an increase of 2,266. 92 per cent. of the deaths occurred among children under 12 years of age, nearly 30 per cent. being infants. Only in four districts did the death-rate from this cause exceed 1 per 1,000, viz., Dera Ismail Khan 1·56, Hissar 1·52, Peshawar 1·33,

and Gurgaon 1·06. In some places outbreaks of the disease were attributed to the operations of inoculators. It was suggested that these men should be induced to give up inoculation and become vaccinators, but the Army Sanitary Commission point out that "experience in other provinces has shown that converted inoculators rarely "become good vaccinators."

Deaths ascribed to fevers were less by 123,120 than in 1894, the number having fallen from 515,238 or 25·07 per 1,000 to 392,118 or 19·08. The provincial rate was exceeded by 14 out of the 31 districts, the highest being recorded by Umballa, viz. 29·14, followed by Kangra 24·37, and Kohat 23·85. In the rural areas the average fever death-rate was 19·15, and that of municipal towns 18·03. Of late years the "mortality from fevers in this province, the Sanitary Commissioner (Dr. Roe) states "seems to be steadier and more nearly approaching the truth than in the early part "of the eighties. This possibly may be due to improved registration, but also and "most probably to drainage works constructed in some of the worst places, and the "arrangements made to avoid the occurrence of heavy floods.

From dysentery and diarrhœa 15,648 deaths were registered, being in the ratio of 0·76 per 1,000 against 17,983 or 0·87 in 1894. The districts showing the greatest mortality under this head were Simla 3·26, Umballa 1·70, Delhi 1·62, Gurgaon 1·44, Kangra 1·31, Amritsar 1·21, Karnal, 1·18, and Gurdaspur 1·12.

Burma.

Some slight progress was made in the registration of vital statistics in Lower Burma during 1895, but there is still much room for improvement. The total number of births recorded was 131,147, equal to 29·04 per 1,000 of the population, which was the highest ratio on record. In the previous year 124,753 births were registered, representing a ratio of 27·62 per 1,000. "The rise in the birth-rate," the Chief Commissioner remarks, "is satisfactory, but it should be remembered that the rate is calculated "year after year on the same basis, namely the census figures of 1891, and "consequently that, unless registration grew annually worse, the returns should show "a slight increase in rate from year to year. The same remark applies to the "death-rate." The district rates ranged from 38·79 in Sandoway to 22·88 in Amherst, and those of towns from 99·95 in Letpadan to 11·56 in Kyaukpyu. The excess of births over deaths was nearly 7 per 1,000.

The year was not specially unhealthy, and there was a small decrease in mortality. The number of deaths recorded fell from 106,740 or 23·56 per 1,000 in 1894, to 101,160 or 22·40. The variations, however, in the district and town rates are so great, ranging from 31·27 in Akyab and 15·88 in Amhurst in the former, and from 58·58 in Letpadan to 9·64 in Gyobingank in the latter, "that the general average for "the province can hardly be regarded as even approximately correct."

Cholera was not so prevalent as in 1894, and the deaths from it fell from 7,428 or 1·64 per 1,000 to 5,150 or 1·14. The disease was present throughout the year and visited all the districts, though two, Tharrawaddy and Tavoy, recorded only two deaths each. It was specially severe in the Akyab district, where the deaths amounted to 1,458, of which 202 occurred in the town, the district rate being 3·50 per 1,000, the highest rate recorded; Myaungmya came next with 3·29, Sandoway 3·16, and Kyaukpyu 2·23, and in four other districts the provincial rate was exceeded. The average rate of towns and rural areas was the same, 1·14 per 1,000. Out of 35 towns 11 escaped cholera altogether.

From small-pox 1,540 deaths were reported in the province, representing a ratio of 0·34 per 1,000, as compared with 1,737 or 0·38 in 1894. Of the 1,540 deaths, 1,280 occurred in the four districts of the Irrawaddy division, Henzada district alone contributing 864, equal to 1·97 of its population. This was the only instance in which small-pox mortality reached 1 per 1,000. As in the preceding two years the disease was prevalent in the four districts of the Irrawaddy division in every month. In all four districts inoculators are reported to be largely at work, and opposition to vaccination except in the Karen villages is very pronounced. Of the total small-pox deaths, just over 80 per cent. occurred amongst children under 12 years of age, infants contributing 22·6 per cent.

The mortality registered under fevers was about the same as in 1894, viz. 48,049 or 10·64 against 48,104 or 10·65. The death-rate was highest in the districts of Akyab (21·28), Thayetmyo (16·55) and Prome (14·77). In five others the provincial rate was exceeded, and in the remainder the rates ranged from 10·15 to 5·80. The death-rate for the towns was 7·57 and for the rural areas 11·08.

Dysentery and diarrhœa accounted for 8,794 deaths, giving a ratio of 1·95 per 1,000 of the population, the highest on record, against 1·92 in 1894. By districts the

highest mortality under this head was 4·40 in Akyab and the lowest 0·44 in Henzada. The Sanitary Commissioner attributes the increase to "more accurate classification," and not to an unhealthy season, for, as already shown, the mortality from all causes was lower than in 1894.

Central Provinces.

The year 1895 in the Central Provinces was not a healthy one, though the mortality was slightly less than in the preceding year. There was a deficiency of rain, which while favouring an abatement of fever, on the other hand caused a scarcity of good drinking water, and brought the usual consequence of cholera and bowel complaints. The dryness of the year also affected the crops, and there having been a series of bad harvests previously, the people suffered from want of food "or eked out a subsistence "with inferior and unwholesome articles of diet."

There was a great falling off in registered births, the number being 317,432 or 33·41 per 1,000, the lowest recorded for 15 years, and 51,454 or 5·41 less than in 1894. Out of the 20 districts all but four showed a decrease in their birth-rates as compared with the previous year, the diminution being due to a lowering of vitality among the population at large caused by hard times. Only three districts recorded rates of over 40 per 1,000, and in 14 the birth-rates were lower than the death-rates. Saugor is quoted as an instance of the influence which unfavourable conditions exercise on the fecundity of the people. In this district less than half the number of births were recorded in 1895 (12,243) as compared with the previous year (24,642), though probably the decrease to some extent was due to defective registration.

The registered mortality of the year was 349,137 or 36·75 per 1,000, against 353,606 or 37·22 in 1894, when influenza and fevers were the main causes of this high mortality. "Excluding the effects of epidemic influenza," the Sanitary Commissioner (Dr. Newman) writes, "and allowing for the lessened mortality from fevers, "it is certain that last year was even yet more unhealthy than its predecessor, and "therefore, the worst of any year, excepting 1889, within the last ten." The district death-rates ranged between 57·06 in Nimar and 22·73 in Sambalpur. The average death-rate in municipal towns was 40·07 as compared with 36·55 in rural circles. Among the former there were 12 with ratios of over 50 per 1,000, including Badnur 78·38, Multai 73·89, the ratios of the other ten ranged from 64·22 to 51·34. There was an excess of deaths over births in 35 of the 47 municipalities.

All the chief diseases except fevers were considerably more fatal than in 1894. The deaths from cholera numbered 15,506, equal to 1·63 per 10,000 of the population, as compared with 7,043 or 0·74 in the previous year. The disease was present in every district, but it was most fatal in Nimar, Narsingpur, and Chanda, which recorded death-rates from it of 7·37, 5·96, and 5·42. Deaths also occurred in every month of the year, the worst months being August, September, and June. It was more destructive in the towns than in the rural areas, the average mortality of the former being 2·33, and that of the latter 1·57. Out of 72 towns, 32 were exempt from the disease, and in several the mortality was low, but others suffered very severely, among them being Badnur with a ratio of 20·14, Lakhnadon 18·79, and Bhandara 15·81.

From small-pox the deaths were unusually high, numbering 6,644 or 0·70 per 1,000, against 1,500 or 0·16 in 1894. The disease was particularly prevalent in the districts of Nagpur, Jubbulpore, and Wardha, where the deaths were equal to ratios of 2·44, 1·56, and 1·45 respectively. Of the total deaths from small-pox 74 per cent. occurred among children under 12 years of age, of whom 30 per cent. were infants. The death-rate in the towns was 1·96 per 1,000, or more than three times that of the rural areas, which was 0·58. Only 13 of the towns were exempt from the disease, while 16 recorded death-rates of over 3 per 1,000.

About two-thirds of the total mortality were ascribed to fevers. The deaths numbered 221,418 or 23·30, showing a decrease of 17,133 or 1·81 on the previous year. The provincial death-rate from fever was exceeded by 12 out of the 20 districts, the highest being 44·52 in Nimar, 36·86 in Saugor, 32·16 in Narsinghpur, 31·41 in Hoshangabad, and 30·14 in Damoh. As usual the worst months were September, October, November, and December. The average town mortality from this cause was 19·32 per 1,000, which was made up of ratios ranging from 57·55 in Charwa in Hoshangabad district to 3·51 in Markher in Nagpur district in Sambalpur. The average rural mortality was 23·68.

The registered mortality from dysentery and diarrhœa was 20,316 or 2·14 per 1,000, as compared with 16,880 or 1·78 in 1894. These complaints were in a marked degree the concomitants of distress, and prevailed chiefly in Jubbulpore, Narsinghpur, Hoshangabad, Saugor, and Damoh, whose death-rates ranged from 4·65 to 3·83. Dr. Newman observes that "it seems very doubtful that even a fair proportion of

" deaths from dysentery are reported as so caused. In looking through village " records I rarely found entries of this disease, and it is often in epidemic seasons " taken for cholera. One Civil Surgeon remarks that the people seldom admit " dysentery as the cause of death, and another says that many more cases occur than " are shown in the registers. Both are, I think, correct."

Assam.

Registration of vital statistics in Assam is still very backward, the figures are therefore unreliable, and useful only for purposes of comparison, a remark which also applies to several other provinces. The total number of births registered during 1895 was 155,631, giving a ratio of 31·0 per 1,000 population, as compared with 156,153 or 31·10 in the previous year. As in 1894 the highest birth-rate was recorded by Goalpara district, viz., 42·29, and the next highest rates were 34·05 and 31·09 respectively registered in the Cachar and Sylhet districts, these being the only three instances in which the provincial rate was exceeded, as the rates of the remaining districts ranged from 29·05 in Lakhimpur to 22·07 in Nowgong. "There is little " doubt," Dr. Stephen, the Sanitary Commissioner, remarks, "that in 1895 not less " than 30 per cent. of the births in this province were not registered."

Deaths were more accurately recorded than births, and taking 42 per 1,000 as representing, approximately, the normal death-rate, the Chief Commissioner estimates that about 19 per cent. escaped registration. The deaths registered during 1895 aggregated 169,304, exceeding the births by 13,673 and the mortality of 1894 by 15,213. The death-rate was 33·72 per 1,000 of population as compared with 30·69 in 1894. In the Surma Valley, comprising the districts of Cachar and Sylhet, the average mortality rose from 27·62 in 1894 to 32·37, both districts contributing to the increase; in the Brahmaputra Valley the average death-rate was 35·33 as compared with 34·04 in the previous year. Of the six districts in this division Goalpara recorded the highest mortality of 42·72 per 1,000, closely followed by Nowgong with 42·28, the ratios of the remaining four districts ranging from 37·76 to 28·82.

Cholera was more fatal than in 1894, the number of deaths having risen from 13,497 or 2·69 per 1,000 to 18,962 or 3·78. The disease prevailed throughout the year and visited every district. Some of the districts recorded a very high cholera death-rate, notably Kamrup and Goalpara in the Brahmaputra Valley with 8·14 and 6·73 respectively. In the Surma Valley districts of Cachar and Sylhet the rates did not reach 3 per 1,000; but the lowest ratio (0·91) was recorded by Nowgong. The average death-rate from cholera in the towns was 4·72 per 1,000. In some of them this ratio was greatly exceeded especially by the Sadr towns of Tezpur and Dibrugarh which registered ratios of 13·46 and 10·63 respectively. Dr. Haffkine's anti-choleraic inoculations were continued up to July 1895, when he left the province, and the work was taken up by Surgeon-Captain Hare. The former inoculated 11,665 coolies on tea gardens, the results showing attacks at the rate of 8·39 per 1,000, and deaths at 3·73 per 1,000, while amongst the non-inoculated 12·13 per 1,000 were attacked, and 7 per 1,000 died. Dr. Hare inoculated 196 out of 355 Khasi coolies, and of these only four were attacked by cholera, but all died. Of the remainder 34 were attacked and 30 died, the ratios per 1,000 of the inoculated who were attacked and died were 20·41 in both cases, as compared with 213·84 and 188·68 respectively for those not inoculated. "The results," the Chief Commissioner observes, "go further than any " yet reported towards establishing the prophylactic efficacy of Dr. Haffkine's system " of cholera inoculation for at least a short period after inoculation."

Small-pox was slightly less prevalent than in the previous year, the deaths numbering 3,849 or 0·77 per 1,000, against 3,997 or 0·80. The highest rates were returned by Goalpara (1·18), and Kamrup (1·11); but though the former was the highest, it was much smaller than in the previous year (6·11), the number of deaths having fallen from 2,762 to 552. The Civil Surgeon of Goalpara reports that villagers persistently refuse to allow their children to be vaccinated. In the Sadr and divisional towns, in most of which vaccination is compulsory, the small-pox death-rate rose from 0·56 to 5·35 per 1,000, the increase being due chiefly to the heavy mortality in Barpeta, a town of about 12,000 inhabitants (where vaccination is not compulsory), which recorded 433 deaths, or 36·43 per 1,000, against nil in 1894. The disease was also severe in Dibrugarh town (11·64). Excluding these two towns, the urban mortality is reduced to 0·22 per 1,000. Of the total small-pox deaths, 25 per cent. occurred among infants, and 53 per cent. among children between the ages of 1 and 12 years.

Over 54 per cent. of year's mortality were ascribed to fevers, including kala-azar. The number of deaths registered from them was 92,359, representing 18·39 per 1,000 of the population, against 85,102, or 16·95 in 1894. There was a considerable increase

in the deaths ascribed to fevers in the Surma Valley districts of Cachar and Sylhet, and in Nowgong. In the last of these three the mortality reached the high rate of 37·17 per 1,000. The next highest fever death-rates were 29·24 and 22·90, respectively returned by Goalpara and Darrang. Of the 15,894 kala-azar deaths, 11,037 occurred in the Nowgong district, an increase of 2,452 on the number of the previous year; it is believed, however, that a large proportion of the deaths returned under kala-azar in this district were due to ordinary malarial fever. Owing to the high mortality from kala-azar in Nowgong and its continued prevalence in other places, a junior medical officer has been appointed with a view to the systematic and continuous observation of the disease.

Under dysentery and diarrhœa 15,523 deaths were registered, yielding a ratio of 3·09 per 1,000 of population, as compared with 14,769 or 2·94 in 1894. As usual, these diseases were most prevalent in Lakhimpur and Sibsagar with death-rates of 7·79 and 5·12 per 1,000 respectively. The mortality reported under these heads in Cachar district was also high, viz., 4·58 per 1·000.

Madras.

The year 1895 was a healthy one in Madras Presidency. The rainfall was above the average, and food prices were lower than in the preceding year, though they were still above the average for the ten years ending 1892. The number of births registered during the year was 976,572 or 29·1 per 1,000, against 933,059 or 27·7 in 1894. The increase was spread over 16 of the 22 districts. Excluding Madras town, which recorded a birth-rate of 42·5, Chingleput registered the highest ratio of 38·4, and in six other districts the rate was above 30 per 1,000, while in Godavari, Malabar, and Ganjam, it ranged from only 24·3 to 17·3. Among the 57 municipalities, two recorded birth-rates over 45 per 1,000, 22 over 35, 20 over 30, and 13 below. The mortality in 1895 was less than that recorded in any of the preceding four years except 1893; the registered deaths numbered 658,719 or 19·6 per 1,000, as compared with 672,668 or 20·0 in 1894. By districts the highest death-rate was, as usual, recorded in Madras, viz., 38·0; "a result which may be partly ascribed to the greater accuracy of the "returns, and partly to the insanitary condition of that city." In the other districts the mortality ratios ranged from 25·0 per 1,000 in Tinnevelly, to 13·6 in Ganjam. The average death-rate of the towns was 27·2 per 1,000, and that of rural areas 19·0.

Of the chief diseases, cholera was considerably less fatal than in 1894, the number of deaths having fallen from 42,289 or 1·3 per 1,000 to 21,172, or 0·6, a lower mortality than had been recorded in any year since 1887. All the districts except Godavari, Kistna, and the Nilgiris were affected, but it was most fatal in Tinnevelly and South Arcot, which recorded 4,649 and 4,307 cholera deaths respectively. The average death-rate in municipal and other towns from the disease was only 0·8 per 1,000, against 2·1 in 1894, and that in rural tracts 0·6, against 1·2. Among the 57 municipalities a total of 1,447 cholera were registered. In nine of them the deaths did not exceed ten in each; while the chief sufferers were Trichinopoly (290 deaths), Chidambaram (216), and Madras and Periyakulam (115 each).

Small-pox deaths were reported from all the districts, but the total in the whole Presidency was only 5,111 or 0·1 per 1,000, against 11,207 or 0·3 in 1894. Of the districts the disease was severe in those of Anantapur, Bellary and Kurnool, which recorded death-rates of 0·5, 0·6, and 0·6, respectively, while in Malabar, where it was very destructive in previous years, the mortality was only 0·03 per 1,000; but the lowest ratio (0·006) was recorded as usual in Madras, where there were only three fatal cases. Of the total 5,111 small-pox deaths 1,111 or 21·7 per cent. occurred amongst children under one year of age, and 1,966, or 38·4 per cent. among those between 1 and 12 years of age.

From fevers the registered deaths showed an increase of 6,881 on the previous year, the number having risen from 270,456 or 8·0 to 277,337 or 8·3; but "in the existing "state of death registration," the Army Sanitary Commission observe, "it is not "easy to say whether this increase was due to greater prevalence of fever, or the "results of increased attention to registration." In four of the districts the fever mortality was over 15 per 1,000, viz., 19·2 in Nilgiris, 18·2 in Vizagapatam, 16·0 in Cuddapah and 15·1 in Kurnool. All these are more or less malarious districts, but, as pointed out, if the ratios of the two first be accepted "it must be supposed that "only 2·5 of the total mortality of 20·7 per 1,000 in Vizagapatam, and 5·7 of that of "24·9 in the Nilgiris were due to any cause but fever." Eleven of the 57 municipal towns returned fever death-rates exceeding 11 per 1,000, the highest being 18·3 in Cuddapah, followed by 14·2 in Madras.

The deaths registered under dysentery and diarrhœa numbered 23,937 or 0·7 per 1,000, against 24,801 or 0·8 in the previous year. The town death-rate under this head was 2·9, as compared with 0·5 in the rural areas; and while, in municipalities, the average mortality was 3·4, in districts it was only 0·7. "Even making "allowance for indifferent registration," Dr. King, the Sanitary Commissioner of the Presidency, writes, "I consider the result sufficiently striking in pointing to the "influence of the usual concomitant of communities living under the evil hygienic "conditions found in most of the municipalities up to date, namely, foul and damp "soil, and water subject to fæcal contamination; where to these conditions the use of "brackish water is added, the incidence of diarrhœa and dysentery becomes greater, "for example, at Vizagapatam, Karur, and Tuticorin, where the rates range from 10·3 "to 7·6, and 6·3 respectively."

Bombay.

In the Presidency of Bombay, including Sind, 674,304 births were registered during 1895, or 14,036 in excess of the number recorded in the previous year, the birth-rates per 1,000 of population being 35·83 and 35·08 respectively. Of the 24 collectorates and districts 15 showed an increase and 9 a decrease as compared with the previous year; but only in seven were the rates over 40 per 1,000, the highest being 47·66 in Ahmednagar, followed by 45·65 in Khandesh. The lowest rates were recorded by Hyderabad (19·32) and Bombay (19·07), the latter showing a slight improvement on the registered rate of the previous year (18·35). There are various exceptional circumstances which account for the low birth-rate of the Presidency city, but the disparity apparently is due to some extent to the omission to register births, for the Government in reviewing the Sanitary Commissioner's report point out that "only last "year the vaccinators discovered 5,617 infants under one year of age whose births "had not been registered." Owing to the healthiness of the year the number of deaths recorded fell from 607,179 or 32·26 per 1,000 in 1894 to 538,540 or 28·61, the average being made up of district rates ranging from 14·62 in Hyderabad to 39·68 in Sholapur. Only in five out of the 24 districts were the recorded death-rates higher than in 1894, the increase in some cases being very trifling.

Cholera was considerably less prevalent in the Presidency in 1895 than in the previous year. Only 8,890 deaths or 0·47 per 1,000 were registered from it as compared with 33,588 or 1·78 in 1894. More than half of the mortality was confined to four districts, viz., Dharwar 1,585, Satara 1,354, Sholapur 1,137, and Khandesh 1,002. The province of Sind was again free from the disease, and in the district of Broach there was only one fatal case and in Surat only five. Deaths occurred in every month of the year, the maximum of 1,652 being reached in August. The average urban death-rate from cholera was 0·44 per 1,000 against 0·48 in the rural areas. More than half the towns escaped the disease, while some were severely affected, notably Pandharpur in Sholapur district, which recorded a cholera death-rate of 17·24 per 1,000. The Sanitary Commissioner with the Government of India (Dr. Cleghorn) observes that "in recent years little has been done to improve the "sanitary state of this town, the energies and money of the municipality being devoted "to the construction of a high school and the building of a bridge."

The number of deaths from small-pox fell from 3,155 or 0·17 per 1,000 in 1894 to 2,299 or 0·12 in 1895. All the districts except Panch Mahals recorded deaths from the disease, but in no case did the mortality reach 1 per 1,000, the highest death-rate being 0·40 in Kolaba. According to age 26·66 per cent. of the deaths occurred amongst infants, whilst 54·59 per cent. took place among children between one and 12 years of age.

The mortality ascribed to fever during the year though much larger than the decennial mean showed a considerable decrease as compared with that of 1894, the deaths numbering 388,848 or 20·66 per 1,000 against 429,094 or 22·80. The average rate of the Presidency was exceeded in 11 districts, among the highest being Sholapur 30·75, Ahmednagar 28·33, Satara 28·15, Khandesh 27·39, and Nasik 25·92. The most striking decrease in fever mortality occurred in the Gujarat Registration District, comprising the collectorates of Surat, Broach, Kaira, Panch Mahals, and Ahmedabad, where the number of deaths fell from 109,183 in the previous year to 70,258. In the towns the average death-rate from fever was 15·62 per 1,000, a ratio made of extremes ranging from 40·67 to 6·05. In the rural areas the average rate was 21·36 per 1,000.

From dysentery and diarrhœa the registered deaths rose from 34,667 or 1·84 per 1,000 in 1894 to 35,348 or 1·88 in 1895. In 12 districts the death-rate under this head showed an increase, and among the highest Sholapur came first with a ratio

of 4·34, Satara 3·88, Belgaum 3·65, Nasik 3·64, and Ahmednagar 3·42. In the remaining districts the ratios ranged from 3·09 in Khandesh to 0·04 in Panch Mahals and in Upper Sind Frontier.

Although the climatic conditions were favourable and food was cheap in Berar during 1895, the public health was not so good as in the previous year. The total number of births registered in the course of 1895 was 105,952 or 37·2 per 1,000 of population, showing an increase of 11,193 or 3·9 on the previous year. In the six districts of the province the birth-rates varied considerably, the largest being 44·2 in Buldana and the lowest 27·3 in Basim and 25·4 in Wun, but all recorded a higher rate than in 1894 except Basim where there was a small decrease of 0·1 per 1,000. Regarding the low ratios recorded by Basim and Wun, the Sanitary Commissioner, Dr. Little, reports that birth registration is most defective in them, though he thinks the falling off as compared with previous years was also due to other causes. He personally examined the registers in several villages of both districts and was struck by the high death and low birth rates recorded, yet in most instances he found the registers were pretty accurately kept. In the towns the average birth-rate was 40·1 and in the rural areas 36·9. Berar.

The deaths rose from 119,561 or 42·0 per 1,000 in 1894 to 141,937 or 49·9, "a rate "which has only been exceeded twice in the last 28 years." The increase of 22,376 deaths occurred chiefly under cholera and dysentery and diarrhœa, together accounting for an increase of 18,093 deaths. As in the case of births Wun district recorded the lowest death-rate (41·6), whilst Basim which came next to Wun in regard to low birth-rate recorded the highest death-rate of 58·4, Buldana coming next with 55·3, the remainder being as follows:—Ellichpur 51·9, Akola 48·6, and Amraoti 47·0. In towns the average death-rate rose from 41·6 in 1894 to 46·4 which was made up of ratios ranging from 76·0 to 32·9. In 14 towns the mortality was excessive, varying between 76 and 53 per 1,000.

Cholera was again epidemic during the year, and was the cause of 11,919 deaths or 4·2 per 1,000 of population against 3,452 or 1·2 in 1894. The disease affected every district, and prevailed throughout each month of the year. According to districts the greatest mortality was recorded in Basim, where there were 3,976 cholera deaths, equal to a ratio of 10 per 1,000, exceeding the mortality registered under this head in the whole province in 1894. Dr. Little notices that in epidemic years this district suffers very severely. "Why this should be so," he writes, "it is difficult "to explain. The local sanitary conditions of the villages in the Basim district are, "if anything, better than those of the other districts in the province, so that local "insanitary conditions do not account for the comparative relative intensity of cholera "epidemics in this district." Next to Basim, the Buldana district suffered the most severely, returning a cholera death-rate of 5·8 per 1,000; Wun district followed with a ratio of 4·5, all three showing a considerable increase on the rates of the previous year; in each of the other three districts also the cholera mortality was higher than in 1894. The average urban and rural death-rates from cholera were 3·2 and 4·3 per 1,000 respectively. Only 11 of the 37 towns escaped the disease, and in five the death-rates exceeded 10 per 1,000.

There was a marked reduction in the mortality from small-pox which is attributed to the spread of vaccination. Only 556 deaths were registered, giving a ratio of 0·2 per 1,000 of population as compared with 1,061 or 0·3 in 1894. The greatest number of deaths (205) was registered in the Buldana district and the fewest (25) in the Basim district. Of the total small-pox deaths 181 occurred in the towns and 375 in rural circles. Ninety-three per cent. of the deaths occurred amongst children under 12 years of age, 205 or 36·9 per cent. being infants under one year.

Under fevers a mortality of 66,203 or 23·2 per 1,000 was registered, against 67,070 or 23·6 in 1894. "A curious feature of this high mortality," the Commissioner observes, "is that it contradicts previous experience in regard to the relation between "rainfall and prevalence of fevers, for the year 1895 was remarkable as being a "peculiarly dry year, with only 27 inches of rain. Yet the ratio of deaths from fever "was 23·2 as compared with a mean of 17·7. We are evidently far from a knowledge "of the seasonal causes of this disease, though its prevalence at certain times is "fairly established." By districts the death-rates from fever varied between 27·7 in Wun and 21·2 in Amraoti. Regarding the high mortality in Wun, Dr. Little again points out that the "district is very malarious owing to the general conditions of the "country as regards forests, uncultivated lands, &c. Endeavours have been made "to alleviate the evil by the sale of cheap quinine, but the aboriginal Shond and Kulam

" inhabitants are too ignorant to avail themselves of the remedy. These people are " very poor, scantily clad, and live from hand to mouth. They usually work as field " labourers, and in seasons of scanty harvest almost starve, sustaining life with jungle " fruits, specially the mowha blossom and the seeds of grasses. They are improvident, " intemperate, and uncleanly, and the mortality amongst them, their young especially, " must be very high."

The number of deaths attributed to dysentery and diarrhœa was 24,452 or 8·6 per 1,000, which shows a great increase on 14,886 or 5·2 recorded in 1894. Ellichpur district, as usual, recorded the highest mortality under this head, viz., 13·8, a ratio which had not been surpassed for 23 years. Akola followed with 10·3, and the other district rates ranged from 9·3 in Basim to 2·8 in Wun.

IV.—JAILS.

Sickness and mortality in 1895.

Judged by the mortuary statistics there was an improvement in the health of the jail population of India in 1895. The daily average sick per 1,000 of average strength rose from 39·29 in 1894 to 42·95, but the ratios of admissions into hospital and of deaths declined from 1,030 and 31·84 per 1,000 respectively, to 1,006 and 26·59. Of the ten provinces, all but Assam, the Punjab, and the Central Provinces, returned a lower jail death-rate than in 1894, the most noticeable cases being Bengal and Coorg. It will be observed from the table below that the mortality was highest in the Central Provinces, Assam, and Coorg. From cholera there were only 93 deaths as compared with 255 in 1893. In the jails of the Punjab, Berar, and Coorg, there were no deaths from this disease. There were more deaths from fevers, and dysentery and diarrhœa.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the several provinces for 1895 as compared with the previous year.

Provinces.	1895.			1894.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,247	42	27·47	1,232	43	47·12
North-Western Provinces and Oudh	902	58	27·45	869	43	32·28
Punjab	1,451	35	21·81	1,758	39	18·73
Burma	892	38	17·93	876	43	28·78
Central Provinces	922	35	55·96	951	34	31·74
Assam	1,287	58	59·21	1,411	56	51·65
Coorg	591	16	42·86	575	24	58·41
Madras	643	26	18·18	628	25	19·85
Bombay	956	30	29·23	810	29	32·07
Berar	877	23	23·26	1,327	50	28·53
India	1,006	43	26·59	1,030	39	31·84

Bengal.

The sanitary history of the Bengal jails for 1895 is on the whole satisfactory. The year's statistics show a material improvement in the health of the prison population of the province, which was no doubt due partly to the healthiness of the year; but the diminished mortality is in great part ascribed "to careful super- "vision, and to the intelligent and effective manner in which local conditions "affecting the health of the prisoners have been met and overcome." The admissions into hospital were in the ratio of 1,247 per 1,000 of average strength against 1,232 in 1894, the average daily sick-rate was 42 or 1 per 1,000 less and the death-rate fell from 47·12 to 27·47, the lowest mortality on record for more than 50 years. Among all classes of prisoners there were 465 deaths, and of these 418 were convicts. The diseases which contributed largely to the convict death-rate (26·3) were dysentery and diarrhœa 155 deaths, respiratory diseases 61, scrofula and phthisis 38, and cholera 26. In the previous year there were 65 deaths from cholera among the convicts. The only serious outbreak of the disease occurred in the Dinajpur jail, where 13 prisoners died out of 15 attacked. Of the convicts who died in jail 27 per cent. were admitted in good health, 31 per cent. in indifferent health, and 42 per cent. in bad health. Out of 47 jails the average death-rate among convicts was exceeded in 22, the highest being 147·18 in Dinajpur against 37·5 in 1894, Chaibassa 126·6 against 239·7, and 105·7 in Chapra against 93·5. In ten others the mortality was over 50 per 1,000, and in four over 40 per 1,000. The high mortality of the Dinajpur jail was due to the outbreak of cholera referred to above, and to the bad state of health

of the prisoners on entering the jail, only 3 out of the 19 who died being admitted in good health. In the Chapra and Chaibassa jails also the condition of the convicts on admission materially affected their death-rates; for, in the former of these two jails, out of 29 deaths only five were admitted in good health, and in the latter out of 15 deaths only three were found to be in good health on admission. Medical committees were appointed during the year to inquire into the sanitary condition of several of the jails in which the mortality was excessive in the previous year, and the recommendations submitted were approved by Government, and some have already been carried into effect. "No pains," it is reported, "have been spared to improve "sanitation where defects could be found, and special attention has been directed to "the jails in which severe outbreaks of disease have occurred, or in which the general "mortality of the prisoners have been excessive. The question of diet has been "prominently before the medical officers during the year, and every opportunity has "been taken to vary the diet or substitute more nutritious food where this appeared "desirable." The water-supply of the jails also continued to receive attention, and steps were taken to remedy defects brought to notice.

North-Western Provinces and Oudh.

The year 1895 in the North-Western Provinces and Oudh being one of much scarcity among the free population, many of the admissions into the jails were in the last stages of want and emaciation. It is not surprising, therefore, the Inspector-General observes "that the sickness and mortality were high, though it will be "noticed that the jail death-rate was lower than in the previous year." The admissions into hospital rose from 869 per 1,000 of average strength in 1894 to 902, the daily average sick-rate from 43 to 58 per 1,000, while the death-rate declined from 32·28 to 27·45; this, however, it is stated, would have been much higher, but for the efforts made by medical officers in district jails to control the mortality. Of the 56 jails in the province, 11 recorded a death-rate of over 50 per 1,000, the highest being 137·07 in Moradabad. This high death-rate formed the subject of a special inquiry, when it was found that there had been great remissness on the part of the prison staff in the dieting of the prisoners. Of the staff's shortcomings suitable notice was taken. The high mortality in the Banda (99·13), Lalitpur (85·10), and Karwi (111·88), jails, was ascribed to the scarcity which prevailed in the Bundelkhand division. Several of the jails showed a distinct improvement in health, among them being the two combined jails of Gorakhpur, where the convict death-rate from all causes declined from 87·19 in 1894 to 39·82. Both the new and old jails were occupied during the year; the new one proved remarkably healthy, and the old one has now been vacated. Of the total 897 deaths in the jails, 836 were of convicts, the death-rate being 27·34. The mortality was highest among convicts during the first six months of imprisonment (35·26 per 1,000), and lowest among those who had been between two and three years in jail (10·36). The first of these is explained, to some extent, by the enfeebled state of health of the majority of the prisoners on admission, many having been sent direct to hospital. Dysentery and diarrhœa were the most fatal diseases among the convicts; the deaths from these amounted to 328; respiratory diseases followed with a mortality of 165, followed by anæmia and general debility, and fevers with 50 each. There was very little cholera in the jails, the deaths numbering only nine, of which three occurred in Fyzabad, and two in Partabgarh.

Punjab.

There was less sickness in the Punjab jails in 1895 than in the previous year, but the mortality was higher, though it was lower than in any of the preceding years except 1894. The admissions to hospital per 1,000 of average strength fell from 1,758 to 1·451, the daily sick-rate from 39 to 35, while the death-rate rose from 18·73 to 21·81, due to pneumonia, and an epidemic of influenza which appeared in many of the jails, but chiefly in the Montgomery Central Jail. Excluding the statistics of this jail, where the mortality was high (51 per 1,000), the average death-rate of the other 32 jails of the province was only 18·42, lower than any rate recorded in past years. But the highest death-rate was returned by the Lahore Female Jail, viz., 60·77, the result of 11 deaths. In four jails there were no deaths, and in 11 the mortality was below 15 per 1,000. In several other jails the death-rates were below the provincial average. Of the total 248 deaths, 105 or 38 per cent. were due to respiratory diseases, 22 being contributed by the Montgomery Jail alone. The disease was most fatal in December, when 45 deaths occurred. Among other diseases, dysentery and diarrhœa had 26 fatal cases, and scrofula and phthisis pulmonalis, 29. There was a marked decrease in the number of admissions under intermittent fever, which the Inspector-General ascribed to "the comparative healthiness of the autumnal months, and

" probably, in some measure, to the administration during the unhealthy season of " fever prophylactics, large quantities of which were supplied to all jails." Among convicts alone there were 235 deaths, equal to 22·05 per 1,000 of average strength, against 18·89 in 1894. Of these 91 had not been more than six months in jail, but the highest rate, according to length of residence, was among convicts who had passed three, and less than seven, years in jail (46·68 per 1,000), though, to some extent, this is accounted for by the fact that 8 out of the 38 prisoners who died at this period of residence were over 50 years of age.

Burma.

The health of the jail population of Burma during 1895 was, on the whole, satisfactory, and the death-rate was the lowest of which there is any record. Among all classes of prisoners the admissions into hospital were in the ratio of 892 per 1,000, against 876 in 1894, the daily sick-rate was 38 or 5 per 1,000 less, and the death-rate was only 17·93 as compared with 28·78 It will also be observed that the Burma jail death-rate for 1895 was the lowest of all jails under local governments and administrations. Apparently no " special measures were taken to obtain this satisfactory result, and it " must be concluded that the low rate of mortality was in consequence of an intelligent " and strict attention to all the ordinary details of jail management." To some extent the greater healthiness of prisoners in this province is accounted for by the people being " on the whole more healthy and better nourished than those in some of the " provinces of India." Of the 245 deaths which occurred during the year, 23 were due to fever, 56 to dysentery and diarrhœa, and 16 to cholera—seven of which took place at Sandoway, and four each at Minbu and Myingyan. The jails of the province continued to enjoy complete immunity from small-pox. Seven of the jails recorded a higher death-rate than the average, the highest being Sandoway, 200 per 1,000; Akyab, 79·23; Pagan, 47·06; and Minbu, 33·9; but the number of prisoners in these jails, except Akyab, is small, and a few deaths give a high rate. In Sandoway the average daily strength was only 35, and in Minbu 118, and the seven deaths in the former and the four in the latter—all due to cholera—accounted for their high death-rates. All but 18 of the total 245 deaths occurred amongst convicts, their death-rate being 17·17 per 1,000, against 28·50 in 1894. It is reported that all the jails except five were more or less overcrowded during the year, and that it was necessary to occupy verandahs and work-sheds as dormitories.

Central Provinces.

The health of the prisoners in the jails of the Central Provinces during 1895 was most unsatisfactory. The admissions into hospital per 1,000 of average strength fell from 951 in 1894 to 922, but the daily average sick-rate rose from 34 to 35 per 1,000, and the death-rate from 31·74 to 55·96, the highest mortality since 1887. It will be observed that the death-rate was out of all proportion to the increase in the sick-rate, denoting, apparently, greater severity in the sickness from which the prisoners suffered. Out of the total number of 277 deaths, more than half (149) were caused by dysentery and diarrhœa, chiefly by a highly fatal and malignant form of the former disease. The new admissions into jail were generally in poor health and low condition, and many of them were admitted at once either into the infirm gang, or into hospital. Almost all the jails recorded a higher mortality as compared with the previous year. Those of Balaghat, Narsinghpur, Seoni, Saugor, Mandla, and Hoshangabad furnished the highest figures, their ratios ranging from 378·5 to 162·5 per 1,000. Among other diseases respiratory diseases caused 36 deaths, fevers 14, and cholera 15. In the previous year there were only two fatal cases of cholera. All but nine of the 277 deaths occurred amongst convicts, the death-rate being 57·65, against 32·36 in 1894.

Assam.

The health of the prison population of Assam in 1895 was not so good a in 1894. The rate of admissions to hospital was somewhat lower than in the previous year, 1,287 per 1,000 against 1,411, but the daily sick-rate rose from 56 to 58, and the death-rate from 51·65 to 59·21. The cause of this high mortality was specially inquired into by the Chief Commissioner, who came to the conclusion that it was due chiefly to the absence of proper supervision over convicts employed extra-murally. Orders were issued for placing the whole system of extra-mural labour on a more satisfactory footing. Of the total 85 deaths among all classes of prisoners, 36 were due to dysentery and diarrhœa, and 11 to intermittent fever. There was only one death from cholera. All but four of the deaths occurred amongst convicts, the death-rate being 61·68 against 53·38 in 1894. Excluding the lock-ups, the average death-rate of the nine jails in the province

was 69·02 per 1,000, as compared with 58·73; but only three, Silchar, Gauhati, and Sylhet, were responsible for the increase, every other jail showing a decrease. The mortality in Silchar, although showing an increase, was not high, but Sylhet returned a death-rate of 81·47 as compared with 45·33 in 1894, and Gauhati 56 91 against 49·68. To some extent the high mortality of Gauhati jail was due to the transfer to it of sickly prisoners from Tezpur.

Madras. There was more sickness among the prisoners in the Madras Presidency in 1895 than in the previous year, but the mortality was lower. The hospital admission rate rose from 628 per 1,000 of average strength to 643, the daily sick-rate was 26, or 1 per 1,000 more, while the death-rate declined from 19·85 to 18·18, being a lower mortality than that of any previous year since 1886. The Inspector-General ascribes the low death-rate to the attention given to the proper feeding of the prisoners, and he states that the cause of undue sickness in jails is neglect in "proper selection, preparation, and "distribution of food to the prisoners. That this is in practice the most important "factor in determining the health of prisoners in jails in this country I am more and more "convinced, and it is evident that the care devoted to the food can never be relaxed, "for while conservancy, drainage, ventilation, and even water-supply, when once "properly settled need not alter, the cooking and distribution of the food may vary "from day to day." The average death-rate of the central jails was again satisfactory, 16·5 per 1,000, and it would have been lower but for the high mortality of the Cuddapah jail, whose death-rate was 50·81. The most unhealthy jail was Parvatipuram, which recorded a death-rate of 123·60 per 1,000. Owing to the persistent unhealthiness of these two jails they were ordered to be temporarily closed during the year. Russelkonda returned the next highest death-rate (44·52), resulting from three deaths among an average strength of 70. Of the remaining 24 jails the mortality ranged from 27·04 to 5·05 in 17, while in seven there were no deaths. Dysentery and diarrhœa and respiratory diseases were the chief causes of mortality among the prisoners, the deaths from the former numbering 56, and from the latter 27, out of a total of 178. From cholera there were eleven deaths, but only in Palamcottah Jail did the disease assume an epidemic form, the number of cases being six of which five proved fatal. The increased sickness of the year was occasioned almost entirely by the great advance among convicts in the admissions from fever, viz., from 190 per 1,000 of strength in 1894 to 251 in 1895. Of the total 178 deaths convicts contributed 165, representing a ratio of 19·26 per 1,000 of average strength as compared with 20·69 in 1894.

Bombay. The general health of the prison population of the Bombay Presidency during 1895 was less satisfactory than in the previous year, though there was a slight fall in the mortality. The rate of admissions to hospital per 1,000 of average strength rose from 810 to 956. The daily sick-rate (30) was 1 per 1,000 more, while the death-rate declined from 32·07 to 29·23 per 1,000. Among the convicts the mortality was 32·2 or only 1 per 1,000 less than in 1894. Eight out of the 18 jails were overcrowded throughout the year, and of these eight three, the Common Prison, Bombay, and the jails of Ahmedabad and Thana, recorded convict death-rates of 42·8, 51·7, and 55·8 per 1,000 respectively. In the Deccan Gang also the mortality (51·0) was considerably above the average. In none of the jails, however, was the mortality nearly so high as the average death-rates formerly recorded for the jails, now closed, at Ahmedabad, Kaira, and Dhuliakot. All but 22 of the total 245 deaths (including 12 in the lock-ups) occurred among the convicts, the chief causes of mortality being, dysentery and diarrhœa 71, respiratory diseases 60, including 51 from pneumonia, fevers 14, phthisis pulmonalis 18, anæmia and general debility 8, and cholera 5. All the cholera deaths occurred in the Deccan Gang and formed a third of its mortality. "Prompt measures," the Inspector-General reports, "were taken in the shape of "stoppage of work, shifting of camp, boiling drinking water, &c., to check the "disease. The cause of the outbreak could not be clearly traced, but as cholera "was prevalent in a neighbouring village it may be assumed that the disease found "its way thence to the Gang camp, although communication between the camp "and the village in question had been prohibited." Pneumonia, as usual, was very prevalent in the Sind jails, 71 cases, or nearly half the total number, having occurred in them. Twenty-nine of the 71 cases took place in Ahmedabad Jail and 20 in Yerrowda, results which call for special measures "for further improvements in the "matter of bedding and clothing for the prisoners."

Berar. The vital statistics of the jails in Berar show that the general health of the prisoners was far better in 1895 than in the previous year. The rate of admissions into hospital

per 1,000 of average strength declined from 1,327 to 877; the daily sick-rate also fell from 49 to 23 and the death-rate from 28·56 to 23·26. Of the six jails in the province the mortality was highest (38·63) in Akola, while in Amraoti, which in respect of population and surroundings was somewhat similar to the jail at Akola, it was lowest, (15·14). Of the total 33 deaths 20 occurred in the Akola Jail, and of these five were due to respiratory diseases, four to dysentery and diarrhœa, three to anæmia and general debility, and three to scurvy. Ten out of the 20 deaths in this jail were among prisoners above 55 years of age. All but one of the 33 deaths occurred amongst convicts, their death-rate being 25·64 per 1,000 as compared with 29·13 in 1894.

V.—VACCINATION.

General results.

During 1895–6 there were 7,223,591 persons successfully vaccinated in the several provinces of India, being an increase of 356,320 on the number of the previous year. According to age, $2\frac{3}{4}$ millions (2,741,708) of the total were children under one year of age, and over $3\frac{1}{4}$ millions (3,369,313) were children between the ages of one and six years. The proportion of population protected against small-pox by the year's operations ranged from 58·52 in Coorg and 42·20 in Assam to 28·49 in the North-Western Provinces and Oudh. In the vaccination of infants the best results were, as usual, obtained in the Punjab, Berar, and Bombay, where 58·8, 58·2 and 58·0 per cent. respectively of the children born during the year (estimated at 40 per 1,000 of population) were protected against small-pox. In the Central Provinces the percentage was nearly 50, and in the remainder it ranged from 30·2 in the North-Western Provinces and Oudh to 17·2 in Coorg, and 14·7 in Bengal.

Statement showing the total number of persons successfully vaccinated during the year 1895–96 :—

Province.	Population among whom Vaccination was carried on (Census of 1891).	Number of Persons successfully vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Children born during the Year (calculated at 40 per 1,000 of Population) successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal - - -	70,761,383	2,200,472	31·09	416,307	1,477,096	14·7
North-Western Provinces and Oudh.	47,146,033	1,343,207	28·49	570,227	614,949	30·2
Punjab - - -	20,724,940	775,972	37·44	487,217	153,692	58·8
Central Provinces - -	12,172,345	438,164	35·99	239,865	121,503	49·3

Coorg - - -	173,055	10,127	58·52	1,188	4,043	17·2
TOTAL - -	226,010,428	7,223,591	31·96	2,741,708	3,369,313	30·3

Bengal.

The total number of vaccinations performed in Bengal during 1895–96 was 2,277,081, of which 2,200,472 were successful, against corresponding figures in 1894–95 of 2,174,097 and 2,089,823. The primary operations numbered 2,227,932, of which 97·84 were successful. According to age, 416,307 of the successful primary vaccinations were of children under one year of age, and 1,477,096 were between one and six years. For the whole province the successful vaccinations were in the proportion of 31·09 per 1,000 of the population against 27·98 in 1894. The death-rate from small-pox was, in 1895, 0·18 per 1,000 as compared with 0·11 in the previous year. Estimating the births during the year at 40 per 1,000, the percentage of infants successfully vaccinated was only 14·7, a ratio far below that attained in other provinces. There was, however, a slight improvement in the protection afforded to infants as compared with the results of the previous year. Three methods of vaccination are practised in the province—(1) with lymph taken direct from the calf; (2) with calf lymph prepared with lanoline; (3) with human lymph taken by arm to arm transfer.

"Speaking from personal experience extending over six years in other provinces, of "all these methods of vaccination," Dr. Dyson observes, "I have no hesitation in "pronouncing very decidedly in favour of vaccination direct from the calf. I see it "stated in previous reports of this Department that lymph 'when properly procured "'by the arm-to-arm process and from healthy children, is of equal value to the "'lymph procured direct from calves.' I am not prepared to admit this; but "even supposing it to be the case, the difficulty is always to procure healthy "subjects . . . . The advantages of direct calf-vaccination are so great, that it "is fast gaining a strong foothold in the public estimation. Three years ago when "I was officiating as Sanitary Commissioner of these provinces, and suggested this "idea for mufassal towns and rural areas, there was immediately a storm of opposition;

" religious prejudices were put forward, and the impossibility of inducing the people " to give up their calves temporarily was said to be insuperable. Judicious " perseverance, however, in some places, in accordance with my expressed conviction " that it would succeed, has gained the day, and I now find on returning to Bengal " that there is scarcely any prejudice in the northern, eastern and lower districts of " the province." As regards the attitude of the people, Dr. Dyson reports that the people seem to be gradually realising the benefits of vaccination, but that there are still places where vaccination is opposed chiefly on sentimental grounds. A considerable step in advance has been made in Faridpur by Dr. Deare, Deputy Sanitary Commissioner, who induced 36,240 Ferazi Muhammadans, including the leaders of the community, to submit to vaccination with lanoline lymph.

North-Western Provinces and Oudh.

Vaccination continued to make steady progress in the North-Western Provinces and Oudh. The total number of persons vaccinated rose from 1,423,703 in 1894–95 to 1,499,253 in 1895–96, and the successfully vaccinated from 1,264,841 to 1,343,207. The proportion of persons protected by vaccination is, however, still very small, the ratio for the year being only 28·49 per 1,000, which is the smallest ratio attained in any province in India. The mortality from small-pox was in the ratio of 0·04 per 1,000 against 0·09 in 1894. Primary vaccinations numbered 1,437,790, of which 90·89 per cent. were successful. Of the 1,305,919 successful primary cases 570,227 were infants and 614,949 were children over one and under six years of age, both figures showing a satisfactory improvement as compared with the numbers of the previous year, which were 562,481 and 574,426 respectively. Estimating the births at 40 per 1,000 of the population, 30·2 per cent. were successfully vaccinated during the year. But, including the figures for children between one and six years, which show that the arrears of unprotected children remaining at one year of age have been largely overtaken within the next five years, the successful primary vaccinations equalled 79·76 per cent. of the births, a " closer approximation to the birth-rate than has ever before been attained."

In previous years the areas of operation had been divided for the purposes of control into three circles, each in charge of a Commissioned Medical Officer, acting as Superintendent of Vaccination and Deputy Sanitary Commissioner. From the 1st February 1896 the number of these officers has been reduced to two, and the areas of control have been re-arranged.

In the first circle, where in some districts vaccination for years past has been more fully established than elsewhere in the province, the average ratio of success of its 27 districts equalled 31·63 per 1,000 of the population, against a mean for the five previous years of 25·29. In the second circle, the average ratio of its 22 districts was 25·74 against a five years' mean of 18·84. The Vaccination Act is in force in all the municipalities, but Dr. Hutcheson says it is not worked as efficiently as it should be. The results, however, show an improvement on the previous year, the ratio of successful vaccinations per 1,000 of population having risen from 34·92 to 38·15.

Punjab.

Vaccination continued to be satisfactorily performed in the Punjab. Altogether there were 923,175 operations performed during 1895–96, showing an increase of 20,320 cases as compared with the results of the previous year. The increase was entirely among primary cases, for the number of re-vaccinations (229,431) was less by 20,771. Of the primary cases, 93·10 per cent. were successful. The number of successful cases among children under one year of age rose from 472,307 or 57·4 per cent. of the births, calculated at 40 per 1,000 of population, to 487,217 or 58·8 per cent. The provincial ratio of persons successfully vaccinated per 1,000 of the total population was 37·44, against 35·48 in the previous year. From small-pox the death-rate for the year was 0·41 against 0·30 in 1894. Buffalo lymph was chiefly used, and during the year 93 per cent. of the vaccinations were performed with it. The difficulty, however, in procuring buffalo calves increases every year, and if animal vaccination is to be continued, the Sanitary Commissioner says, steps must be taken to meet it. He believes, however, that the difficulty can be overcome by substituting preserved for fresh lymph, experiments made during the year having shown that lymph preserved in vaseline has many advantages over fresh lymph. High caste Hindus willingly permit their children to be vaccinated from it, and thus it may fairly be said we have succeeded in overcoming in great measure the caste prejudices of the people against these operations.

Burma.

Good progress was again made in the extension of vaccination in Lower Burma during 1895–96. The total number of persons vaccinated was 245,065, as compared

with 208,060 in the previous year. The increase of 37,005 was contributed by 11 of the 20 districts, but chiefly by Prome, where the excess amounted to over 10,000 operations. The percentage of success in primary operations continued to improve. Out of 216,759 primary cases, 91·22 per cent. were successful, against a corresponding ratio of 90·96 in the previous year. The number of infants protected was 41,107, equal to about 22 per cent. of the births, estimated at 40 per 1,000 of the population. The total successful vaccinations per 1,000 of population were in the ratio of 39·39 as compared with 33·37 in 1894. The death-rate from small-pox declined from 0.38 to 0·34.

At the end of the year the Vaccination Act was in force in all but four of the 27 municipalities, most of them having voluntarily applied for its extension. Its benefits are less appreciated in rural tracts, because its efficacy is not so well understood; but the large increase in the number of operations within the last four years—the successful primary cases having nearly doubled—is a sign "that the popular "distrust, such as it is, is being gradually overcome."

In Upper Burma 120,678 vaccinations were performed during 1895–96, being an increase of 858 on the number of the previous year. But though the increase was small the quality of the work showed a great improvement, the percentage of success in primary vaccinations having risen from 88·97 in the previous year to 92·63. Estimating the births at 40 per 1,000 of population 22·0 per cent. were successfully vaccinated, practically the same as in 1894–95. The Vaccination Act was extended to four municipalities and four cantonments during the year. In the province of Burma as a whole the ratio of successful vaccinations per 1,000 of population was 39·39, as compared with 33·37 in the previous year, and the percentage of infants successfully vaccinated, estimating the births at 40 per 1,000 of population, was 22·0, an increase of 5 per cent. on 1894–95.

Central Provinces.

In the Central Provinces there were 465,475 persons vaccinated during 1895–96, showing a decrease of 23,790 on the number of the previous year. Primary vaccinations fell from 432,280 to 397,261. The percentage of success in primary cases was 96·22, against 96·27, and the proportion of the total population protected by vaccination was 35·99, as compared with 36·58 in 1894–95. As previously stated, the mortality from small-pox was unusually high, 0·70 per 1,000 against 0·16 in 1894. Of the 18 districts in the province 15 showed a decrease in primary operations, and three an increase. Vaccination from the calf continued to make steady progress, and in some districts had almost superseded the use of humanised lymph. In the protection of infants there was also a falling off, the number vaccinated under one year of age during the year having decreased from 262,916 to 239,865. No additional municipalities were brought under the Vaccination Act during the year, the number remaining at 25.

A new arrangement for the supply of lymph was initiated and carried out during the season with entire success. Instead of organising, as had been previously the custom, a manufacture of lanoline paste from the product of buffalo calves, each Civil Surgeon now produces at his head-quarter station a sufficient supply of calf lymph with which to provide his vaccination establishment at the commencement of the working season. A supply of calf lymph sent out from England was distributed, but, except in one case, it proved inert. With the lymph obtained from calves, 283,759 vaccinations were performed during the year, and 264,834 were successful.

Assam.

The results of vaccination work in Assam for 1895–96 compare favourably with those of the previous year. There were 260,690 operations performed by all agencies in the province, which is an increase of 60,553 over the figures of 1894–95. All the plains districts contributed to the increase, but there was a falling off in the hill districts, especially in the Naga Hills. The largest increase occurred in the Sylhet district (24,182), followed by Sibsagar (11,423). In the Manipur State also there was an increase of 5,633, which is highly satisfactory, as the State has at times suffered very severely from small-pox. Of the total operations 253,641 were primary cases, and of these 96·9 per cent. were successful, this high rate being attributed to the improvement in the lymph supplied from the Shillong Bovine Lymph Depôt. The Compulsory Vaccination Act was extended during the year to the station of Shillong, and Act XIII was at the same time brought into force in the cantonment of Shillong. With these additions there are ten places under the Acts, their population being 68,847. The number of infants successfully vaccinated was 47,176, representing only 20·9 per cent. of the births, estimated at 40 per 1,000 of the population. The ratio of persons protected by vaccination per 1,000 of population was 42·20 against 28·09 in the previous year; the death-rate from small-pox declined from 0·80 to 0·77 per 1,000.

The aggregate number of vaccinations performed in the Madras Presidency during 1895–96 was 1,198,171, being a decrease of 751 on the operations of the previous year. Of the total, 1,120,625 were primary cases, of which 91·22 per cent. were successful, against 91·60 per cent. in 1894–95. The number of children under one year of age successfully vaccinated rose from 297,723 to 314,117, which represented only 22·0 per cent. of the estimated births, as compared with 20·8 per cent. in the previous year. Vaccination was compulsory in all municipalities, and the number of operations performed by municipal vaccinators rose from 118,135 to 120,190. In the town of Madras there was an increase in the number of operations performed, from 24,725 to 27,024. Of the 21 districts there was a decrease of work in 10, the most marked case being that of Vizagapatam (12,207); the remaining 11 districts showed an improvement, the largest increase being 9,034 in Coimbatore. Animal vaccine was employed both in districts and municipalities, and the total number of vaccinations performed with it was 1,190,541, or only 7,630 less than the total number of operations, and of these 1,074,919, or 92·3 per cent. were successful, the corresponding figures for the previous year being 1,164,150, 1,053,993, and 92·5 respectively. The best results were obtained, as usual, from calf-to-arm vaccination, with a percentage of success of 97·3. The ratio of successful vaccinations per 1,000 of population was 30·31 per 1,000 against 29·7 in 1894; the death-rate from small-pox was only 0·1 per 1,000 as compared with 0·3. Madras.

Omitting the statistics of five Native States which are not under the supervision of the Bombay Vaccination Department the out-turn of vaccination work in the Presidency rose from 773,526 operations in 1894–95 to 810,804 in 1895–96. This gives an increase of 37,278, of which 20,292 occurred in primary vaccination, and 16,986 in re-vaccinations. The total primary cases rose from 712,356 to 732,448; the percentages of success being respectively 93·48 and 93·23. The substitution of animal for human lymph continued to increase in the Presidency. It is satisfactory to learn that this mode of vaccination is appreciated. In the City of Bombay vaccination with animal lymph exclusively was carried on throughout the year. Of the 683,044 primary successful cases, 72 per cent. were infants under one year of age, and reckoning the births at 40 per 1,000 of population, 58 per cent. were protected from small-pox. Inoculation was not practised anywhere in the Presidency during the year, except in the Dangs. The successful vaccinations per 1,000 of population rose from 30·68 in the previous year to 31·85; the death-rate from small-pox fell from 0·17 per 1,000 to 0·12. Bombay.

There was a still further falling off in the out-turn of vaccination work in Berar during 1895–96, the total operations having decreased from 114,639 in 1894–95 to 106,605. The number of primary vaccinations was 92,694, out of which 95·92 per cent. were successful, against 93,296 and a rate of success of 94·67 in 1894–95. The decrease of 602 primary, and 7,432 re-vaccinations was attributed to the unhealthiness of the two preceding seasons, as shown by the death-rates of 42·0 in 1894 and 49·9 in 1895. Influenza being very prevalent throughout the province there was also much sickness among the general population as well as amongst the vaccinators. "In sickly years," the Sanitary Commissioner writes, "the infantile population being most susceptible "suffers most, consequently there are fewer children available for vaccination, and "this is a fact which must be taken into consideration when measuring the work of "any one year with another; for, as has been pointed out in previous reports, primary "operations, considering the proportion of the population already protected, must of "necessity fluctuate with the number of infants available for operation." Of the total number of successful primary operations, 67,439 were performed on infants under one year of age; estimating the births at 40 per 1,000 of population, 58·2 per cent. were protected from small-pox. The Sanitary Commissioner furnishes a statement showing the efficacy of vaccination in checking small-pox mortality in Berar; the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of five years 1868–69 to 1872–73, to 35·8, the mean of five years ending 1892–93; the mortality from small-pox for the same periods has declined from 2·02 to 0·2 per 1,000. The corresponding ratios for 1893–94 were 35·0 and 0·06 per 1,000, those for 1894–95 were 32·2 and 0·37, and for 1895–96 the ratios were 31·8 and 0·2 respectively. The proportion of the population successfully vaccinated was 31·81 per 1,000, against 32·19 in the previous year. The Vaccination Act is in force in all the municipal towns except Karinja, and is reported to be working satisfactorily. Berar.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries open in the several provinces of India during 1895 and the previous year, and the number of patients under treatment:—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1895	427	45,243	2,434,536	2,479,779
	1894	383	43,824	2,241,626	2,285,450
Calcutta and Howrah	1895	12	26,879	266,672	293,551
	1894	12	24,912	264,041	288,953
North-Western Provinces and Oudh	1895	340	61,514	3,955,681	4,017,195
	1894	336	59,366	3,882,395	3,941,761
Punjab	1895	257	56,172	3,204,445	3,260,617
	1894	255	56,254	3,423,669	3,479,923
Burma	1895	93	30,607	602,380	632,987
	1894	88	28,864	542,061	570,925

	1894	307	48,824	2,389,685	2,438,509
Berar	1895	46	4,912	346,443	351,355
	1894	46	4,804	344,778	349,582
TOTAL	1895	2,211	348,334	19,054,777	19,403,111
	1894	2,123	340,264	18,588,038	18,928,302

Bengal.

The returns of the charitable dispensaries in Bengal for 1895 show a still further increase both in the number of institutions and in the number of patients under treatment in them. The total number of dispensaries at work during 1895 in Bengal, exclusive of the medical institutions at Calcutta, was 427, an increase of 44 on the number of the previous year. At these there were 2,479,779 patients under treatment, 45,243 being in-door and 2,434,536 out-door patients, against 43,824 and 2,241,626 respectively in the previous year. This shows a total increase of 194,329, which was attributed partly to the opening of new dispensaries and partly to the increasing popularity of the institutions. These figures, however, fall short of those for the North-Western Provinces and the Punjab, though Bengal has more dispensaries than any of the other provinces. "One of the chief causes of low attendance in Bengal," the Inspector General observes, "is the large number of private practitioners and "druggists' shops which exist in all parts of the province. Anyone with a smattering "of medical knowledge, and even without it, can and does set up as a private "practitioner. There is absolutely no prohibition in this respect, and I believe there "is actually a so-called Medical School in Calcutta which grants medical diplomas, "although it has no charter and is not even affiliated to the University or to any "recognised medical institution. The result is a flood of ignorant indigent practi-"tioners let loose amongst a prosperous population. This in itself is sufficient to

" account for a low attendance at the dispensaries." There was again a satisfactory increase in the number both of women and children, but the number of males was nearly four times that of females. The increase among women, though not so great as in the previous year, amounted to 36,362 or 10 per cent., the number having risen from 362,632 to 398,994. Of the diseases under treatment at the dispensaries, cholera, dysentery, and malarial fevers were responsible as usual for the largest number of cases. From malarial fever the cases rose from 473,362 in 1894 to 525,300, equal to 21 per cent. of the total number of patients; but cases of dysentery decreased from 87,243 to 59,757, and the number of cholera patients from 12,181 to 11,497. Cases of venereal diseases rose from 55,818 to 57,008. Among in-door patients the deaths rose from 5,051 or 115·2 per 1,000 of total treated in 1894 to 5,568 or 123·1 in 1895. Great attention is paid in these institutions to surgery, and during the year 13,026 major operations were performed against 10,912 in 1894; including those remaining from the previous year, the total number was 13,334, and of these 201 terminated fatally. Operations for cataract increased from 2,323 to 2,861, and of these more than 80 per cent. proved successful.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta during 1895 and the previous year:—

Name of Institutions.	1895.				1894.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.
Medical College Hospital	6,951	58,441	65,392	107·7	7,044	57,906	64,950	102·6
Presidency General Hospital	3,124	519	3,643	53·4	3,031	303	3,334	48·1
Campbell Hospital	9,186	26,303	35,489	245·5	8,440	25,176	33,616	237·0
Police Hospital	2,982	—	2,982	6·7	2,305	—	2,305	10·4
Mayo Native Hospital	2,000	31,431	33,431	93·0	1,856	29,974	31,830	115·3
Chandney Hospital	367	45,309	45,676	57·2	338	44,762	45,100	38·4
Park Street Dispensary	—	30,158	30,158	—	—	31,977	31,977	—
Chitpore Dispensary	—	24,908	24,908	—	—	23,403	23,403	—

Dufferin Victoria Hospital	520	8,315	8,835	7·6	304	10,706	10,706	13·1
Bhawanipur Dispensary	—	11,023	11,023	—	—	9,035	9,339	—
Total Calcutta Hospitals and Dispensaries	25,130	254,981	280,111	135·9	23,318	252,928	276,246	134·9
Howrah General Hospital	1,749	11,691	13,440	245·2	1,594	11,113	12,707	225·2
Grand Total	26,879	266,672	293,551	143·2	24,912	264,041	288,953	140·8

The figures for 1895 show an increase of 2,631 in out-door patients, and of 1,967 in in-door patients. The increase in the former was attributed partly to improved accommodation in the Medical College Hospital, and partly to the growing popularity of the out-door departments of the several institutions. The death-rate among the in-patients was 143·2 per 1,000 against 140·8 in 1894. Cholera patients rose from 567 to 600, and the fatal cases from 323 to 349. There was a great epidemic of small-pox during the year and the cases rose from 177 to 765, and of these 279 terminated fatally. Dysentery and diarrhœa were not so prevalent, and the number of patients fell from 17,838 to 16,689. The number of cases of malarial fever rose from 53,785 to 59,256. Venereal diseases show an increase of 255 patients, the number treated having risen from 13,419 in the previous year to 13,674. There were 3,775 important surgical operations performed against 3,643 in 1894, and of these death ensued in 124 cases against 129.

North-Western Provinces and Oudh.

During 1895 five new dispensaries were opened and one was closed in the North-Western Provinces and Oudh, bringing the total at the end of the year up to 340. The number of patients who received medical aid was 4,017,195 against 3,941,761 in the previous year. There was thus an increase in 1895 of 75,434 patients. Of these 14,144 were treated in the newly opened dispensaries, leaving an actual increase of 61,290 cases or 1·5 per cent. to the credit of those previously established. Notwithstanding this testimony to the growing popularity of hospitals and dispensaries in the province, the conclusion that ignorant prejudices still militated against the complete utilisation of medical relief is shown by the fact that Hindus though constituting 86 per cent. of the inhabitants continued to resort to it in only twice the number of

Mussulmans. Of the total number 774,180 were women, and 1,064,524 were children, both showing a marked increase on the figures of the previous year, which were 755,353 and 1,035,065 respectively. The in-door patients numbered 61,514 as compared with 59,366 in 1894, and among them there were 3,502 deaths, giving a death-rate of 56·9 per 1,000 against 3,469 or 58·4 in the previous year. Of the diseases for which the patients were treated 683,136 were suffering from malarial fevers, a decrease of 3,926 on the number of 1894; cases of cholera declined from 11,255 to 2,743, and cases of diseases of the eye increased from 307,025 to 319,838. From venereal diseases there were 78,640 patients against 77,368 in the previous year. The progress of surgical work kept pace with the general increase in the number of patients applying for relief. The number of surgical cases rose from 182,349 to 192,582. These included 30,633 major operations (with 1,026 remaining from the previous year), of which 24,340 resulted in cure and 436 were fatal. Of the 30,633 major operations 10,565 were for cataract, of which 84 per cent. were successful, as compared with 9,222 operations and a percentage of success of 84·8 in 1894.

Punjab. Two more dispensaries were at work in the Punjab during 1895 than in the previous year, bringing the total number of these institutions up to 257. At these, 3,260,617 patients were under treatment, being a decrease of 219,306 on the number of 1894. The decrease, however, was chiefly among out-patients, the number of in-patients (56,172) being practically the same as in the previous year (56,254). The year was much more healthy than the previous one, and this is the main cause of the smaller number of applicants for advice and treatment. Of the diseases for which patients sought relief there were only 21 cases of cholera, being a decrease of 29 on 1894. Cases of malarial fever fell from 629,853 to 438,166. Diseases of the eye showed a decrease of 33,303 cases, the number treated in 1895 being 355,819 against 322,516. From venereal diseases there were 33,836 cases under treatment, a decrease of 4,995 on the previous year's figures. Among the in-patients there were 2,431 deaths during the year, being in the ratio of 43·3 per 1,000 of the number treated against a death-rate of 44·0 in 1894. In surgical work minor operations decreased from 216,730 to 214,655, and those of a major kind increased from 19,812 to 20,094. Including those remaining from 1894, the latter numbered 20,468. Among these there were 6,335 cases of extraction of the lens, including 119 remaining under treatment from the previous year, of which 87·8 per cent. resulted in cure.

Burma. Two new dispensaries were established in Lower Burma during 1895, bringing the total up to 43. At these 396,458 patients attended, as compared with 355,897 in 1894. In-door patients rose from 18,812 to 20,675, of whom 15,522 were cured, and 1,271 or 60 per 1,000 died, against 1,612 deaths or 90 per 1,000 in the previous year. The total number of Burmans treated was 211,551, exceeding the number of 1894 by 33,276, and there was an improvement in the attendance of the other classes also. Malarial fevers were again responsible for over one-fifth of the attendance. Small-pox cases rose from 143 to 197; while, on the other hand, cholera cases fell from 594 to 213. Surgical work also showed an increase both in major and minor operations, the former having risen from 699 to 808, and the latter from 9,513 to 10,159. The number of patients cured, after being subject to major operation, was 690, and the deaths numbered 22.

In Upper Burma 50 dispensaries were working in 1895, or three more than in the previous year. The total number of patients under treatment was 236,529, of whom 9,932 were in-patients, the corresponding figures for 1894 being 215,028 and 10,052 respectively. In the course of the year 8,052 patients were cured, 624 relieved, 272 discharged otherwise, and 518 died, the deaths yielding a ratio of 50 per 1,000, against 60 in 1894. The Burmese resort to these institutions in greater proportion than in Lower Burma, the percentage of Burmese to total treated being 53·4 per cent. for the lower part of the Province against 62 per cent. in the upper part.

Central Provinces. There was no change in the number of hospitals and dispensaries at work in the Central Provinces during 1895, it remained at 117. The total number of patients rose from 1,202,497 to 1,261,590. The increase extended to both in and out door patients, the former having risen from 10,872 to 12,224, and the latter from 1,191,625 to 1,249,366. Among the in-patients there were 1,321 deaths, or 113·8 per 1,000 of total treated, an increase of nearly 20 per 1,000 on the mortality of 1894, which was "caused by the admission of destitute paupers, very frequently in a moribund condition." As regards the different kinds of diseases treated the statistics do not

exhibit many features that call for notice. Malarial fever, ulcers, and diseases of the eye and skin were responsible, as usual, for the largest number of cases treated. There were 31,416 surgical operations performed against 29,311 in 1894. Of these, 3,593 were major against 3,260. There has been a marked increase in purely surgical work during the last two years. In 1894 the increase of major operations was 55 per cent. in excess of the number in the preceding year, and in 1895 the annual increase was over 10 per cent. In the operations for cataract there has been a considerable increase, viz., from 479 in 1893 and 949 in 1894 to 1,299 in 1895.

Assam.

In the province of Assam there were 97 dispensaries open during 1895, at which 544,938 patients were under treatment against 503,984 in the previous year. The in-patients numbered 5,987, as compared with 5,757 in 1894, and of these 2,935 were cured, 575 relieved, 1,137 discharged otherwise, and 1,127 died, the latter representing 188·2 per 1,000 of the total in-patients, against a ratio of 180·1 in 1894. The increase of 40,954 in the number of patients treated was attributed to the growing popularity of these institutions. It is satisfactory to note that there was a slight increase of 107 among the indigenous population who resorted to the dispensaries as in-door patients, the number having risen from 1,526 to 1,633. The progress made within the past decade in the extension of the system of bringing medical relief to the poor of Assam by means of dispensaries may be gathered from the fact that the number of these institutions has increased from 46 to 97 and the total number of patients from 149,051 to 544,938, or by more than 265 per cent. Of the total number of persons who received medical aid, malarial fever, including kala-azar, accounted for 120,255 cases, or nearly a fifth of the total treated; skin diseases 127,836, worms 78,722, dysentery and diarrhœa 28,462, and diseases of the digestive system 26,524. Cholera patients numbered 1,786, against 1,418 in 1894. Of surgical cases there were 12,349, including 1,126 major operations; of the latter, 978 resulted in cure, and 41 were fatal.

Madras.

Exclusive of the hospitals in the Presidency town there were 486 dispensaries working in Madras at the close of 1895, or 13 more than in 1894. The results of the year were again satisfactory, showing that 3,839,354 patients were under treatment as compared with 3,735,269 in 1894. There was thus an increase of 104,085. Of the 38,422 in-door patients, 23,484 were returned as having recovered fully under treatment, 7,486 as relieved, and 3,474 as otherwise discharged. The deaths numbered 2,265, representing a ratio of 58·9 per 1,000 of the total in-patients against 65·7 in the previous year. The largest number of admissions was from skin diseases, of which there were 450,897 cases; ulcers came next with 411,381 cases, followed by malarial fevers with 398,885 cases, and diseases of the eye with 344,331 cases. The surgical operations aggregated 134,380, including 7,385 of a major kind, of which latter 5,969 were cured and 208 terminated fatally. In 1894 the minor operations numbered 124,785, and the major 5,542.

In the 12 hospitals of Madras town, the number of sick treated increased from 199,305 in 1894 to 193,527 in 1895. The increase of 5,778 was entirely among out-patients as the number of in-patients fell from 19,480 to 17,345. Amongst them 8,415 cases were recorded to have been cured or perfectly recovered, 4,171 were relieved, 2,832 discharged otherwise, and 982 or 56·6 per 1,000 died, against a rate of mortality in 1894 of 57·9. Of the several diseases for which the patients were treated, malarial fever contributed 23,133 cases, followed by diseases of the digestive system and respiratory system with 18,737 and 13,948 cases respectively. From cholera there were only 57 cases, from dysentery and diarrhœa 6,045, and from venereal diseases 4,750, of which 1,378 were afforded in-door relief. The surgical work performed in 1895 compares favourably with that of the previous year, the minor operations having increased from 13,615 to 23,561, and the major operations from 3,794 to 4,154. The results of the latter showed that 2,680 cases were cured, 1,074 relieved, and 141 were fatal.

At the Madras Voluntary Venereal Hospital, which is included in the above hospitals in the city, there were 703 patients treated during 1894, an increase of 41 on the number of the previous year. The Superintendent writes: "The hospital is "well known and popular, and many of the patients come from distant districts. "There was no overcrowding during the year, the greatest number of sick on one "day being 88, while the number of beds is 100. . . . . As a rule the women "remain a long time under treatment. Those who are too sick to follow their "profession are only too willing to remain in hospital. Many have no friends and "continue in hospital till they die."

Bombay.

Excluding the 11 medical institutions in the city of Bombay, there were 306 hospitals and dispensaries working in the Presidency during 1895. At these 2,382,069 patients were under treatment, of whom 30,848 were in-door and 2,351,221 out-door patients, against 30,281 and 2,297,317 respectively in 1894. Malarial fevers as usual constituted by far the largest number of cases (434,118, or nearly 19 per cent. of the total treated), still there was a decrease of 29,187 when compared with the figures of the previous year. Next to fever, eye and skin diseases, and worms were the most common ailments. Small-pox and cholera patients were fewer, but dysentery and diarrhœa cases were more numerous; while patients suffering from venereal affections declined from 33,104 in 1894 to 31,911 in 1895. Of the in-door patients 20,890 were cured, 2,414 relieved, 2,339 discharged otherwise, and 1,543 died, the ratio of deaths to total treated being 54 per 1,000, a decrease of 3 per 1,000 on the ratio of the preceding year. The numbers of both major and minor operations performed during the year were much larger than in 1894. Apart from the 155 cases which remained under treatment from the previous year, 6,305 major operations were performed during 1895, giving a total of 6,460 or 1,173 more than in 1894. Of these 3,955 were cured, 266 relieved, and 118 proved fatal. The total number of minor operations was 107,733 as compared with 99,563 in 1894.

The total number of patients treated at the 11 civil medical institutions working in the town of Bombay during 1895 showed a decrease of 2,964, the figures being 107,947, against 110,911 in the previous year. The in-patients decreased in number from 18,543 to 16,838, and of these 10,301 were cured, 2,863 relieved, 1,111 otherwise discharged, and 1,614 died, the deaths being in the ratio of 95 per 1,000 of the in-patients, against 89 per 1,000 in 1894. As usual, local injuries, malarious fevers, eye diseases, and skin diseases were responsible for the majority of the cases. Venereal diseases contributed 5,251 cases, against 5,497. Cholera cases fell from 88 to 2, and those of dysentery from 1,825 to 1,571, but cases of diarrhœa rose from 3,245 to 3,260. Including 103 cases which had been operated on in the previous year, the total of major operations was 2,515, and of these 2,097 were cured, 129 relieved, 64 discharged otherwise, and 121 ended fatally. The minor operations numbered 31,386, as compared with 28,828 in 1894.

Berar.

There were 46 medical institutions at work in Berar during 1895. Of these eight are hospitals wholly maintained by the State. The total number of patients under treatment was 351,355, against 349,582 in 1894. In-patients numbered 4,912, of whom 4,069 were cured, and 291 died, which gives a death-rate of 59·8 per 1,000 as compared with a mortality of 244, or 50·8 per 1,000 in 1894. Malarial fevers continued to head the list of diseases from which relief was sought, but the cases fell from 90,470 in 1894 to 81,683; about a fourth of the total patients were treated under this head; diseases of the eye and skin came next in order. Cholera cases rose from 1,120 in 1894 to 3,366; there was also a much larger number of admissions from bowel affections. There was a falling off in surgical work; the number of major operations performed having decreased from 705 in 1894 to 630 in 1895, and of minor operations from 12,899 to 11,493.

The Dufferin Hospital for women and children at Amraoti, which was opened on the 15th February 1895, showed good results. The in-door patients during the year numbered 96, and the out-door 6,215.

Lunatic Asylums.

Bengal.

At the five asylums in Bengal (viz., Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,107 lunatics, including 184 fresh admissions and re-admissions, were under treatment in 1895, being a decrease of 9 on the number of the previous year. In the course of the year under notice 81 patients were discharged as cured, and 30 as improved or otherwise, and 75 died. Compared with the figures of 1894, the number discharged was less by 5, while the mortality was the same. At the end of the year there were 921 persons still under detention, or 2 less than at the close of 1894. The health of the inmates of the asylum was not so good as in the previous year, the average daily number of sick being 58, against 55 in 1894, and the number of admissions into hospital more numerous by 276. The death-rate, however, was slightly lower, viz., 81·5 per 1,000 of average strength, against 81·9. Exclusive of Cuttack Asylum, in which there were no deaths during the year, the average rate of mortality was made up of individual asylum rates varying between 71·5 and 97·7 per 1·000. Satisfactory progress appears to have been made in the working of dairy farms at

the asylums. From Dullunda a profit of Rs. 1,092 was reported, and the Dacca Asylum, besides affording a sufficient supply of milk to its inmates, realized Rs. 550 from the sale of milk to the public. The calves were also utilised for supplying vaccine lymph to the asylum, the jail, and the outside population. The question of amalgamating the asylums, and of forming a central asylum for all lunatics in Bengal, under the management of a specially qualified officer, was said to be under the consideration of Government. "In such an institution more attention could be given to the "systematic treatment of mental diseases than is possible under the present system, "and the Lieutenant-Governor hopes that a practicable scheme will soon be drawn "up."

In the Bhowanipur Asylum, containing European and Eurasian patients only, the inmates during 1895 numbered 54, against 64 in the previous year. Of this number 39 were under detention at the beginning of the year, and 15 were subsequently admitted, including 3 criminal lunatics. In the course of the year 10 patients were discharged cured, 2 were dispatched to Europe under the Merchant Shipping Act, 5 were transferred to the care of friends, 1 was despatched to Europe as a civil pauper lunatic, and 4 died, leaving 32 under confinement at the close of the year. The health of the patients was exceedingly good throughout the year, there were only 8 admissions to hospital, and 5 deaths. The proportion of deaths to average strength was 106·2 per 1,000, against 148·6 in 1894.

North-Western Provinces and Oudh.

The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the North-Western Provinces and Oudh in 1895, were 1,289, including 259 admissions during the year, against 1,298 in 1894. Before the close of the year 161 patients were discharged, of whom 112 were reported as cured, 49 were made over to friends, and 80 died, leaving 1,045 under treatment at the end of the year. The health of the asylum population was much better than in the preceding year, and the death-rate per 1,000 of average strength fell from 92 to 79, which was made up of ratios varying from 45 per 1,000 at Bareilly to 133 per 1,000 at Benares. Dairy farming was again very successful at Bareilly. This farm was started towards the close of 1890, with a view to reducing the danger of enteric fever and cholera among British troops by enabling them to obtain a purer supply of dairy produce. Besides giving employment to the inmates of the asylum, it has been of great use to the garrison and Civil Station of Bareilly.

Punjab.

The total number of lunatics in the Lahore and Delhi lunatic asylums in the Punjab during 1895 was 478, including 136 fresh admissions, against 480 in 1894. At the end of the year the number was reduced to 329 by the discharge of 98 patients (60 as cured, 32 made over to friends, and six otherwise discharged), and 51 deaths. The year being a fairly healthy one, there were fewer admissions into hospital, but deaths were more numerous in the Lahore Asylum than in 1894. The total number of hospital cases was 593. In Lahore the cases fell from 517 in 1894 to 492, while the deaths rose from 24, or 101·6 per 1,000 of daily average strength, to 40, or 168·0. Pneumonia was the chief cause of mortality in this asylum, and accounted for 14 deaths. In the Delhi Asylum there were 11 deaths or 98·8 per 1,000, against 18 or 171·2 in 1894. Both asylums were again entirely free from cholera in 1895. The Superintendent of the Lahore Asylum attributed the high mortality to the bad state of the barracks. The execution of improvements contemplated were deferred until a decision had been arrived at on the possibility of amalgamating the two asylums in a provincial asylum at Lahore.

Burma.

The Rangoon Asylum is the only one in the province of Burma. Until the year 1894 a number of lunatics were, for want of accommodation, confined and treated in the Rangoon central jail. The asylum has since been extended, and there is now accommodation for 350 insanes. The whole of the buildings were fully occupied, and more have since been sanctioned. During 1895 there were 437 patients in the Rangoon Asylum, including 106 fresh admissions, and the total was reduced at the close of the year to 350 by the discharge of 51 patients for different causes, and the death of 36. There was considerably less sickness among the patients than in 1894, and the admissions to hospital fell from 275 to 129. The mortality, however, was higher, the deaths having risen from 26 to 36. Of these 5 were from beri-beri, and 2 other deaths were homicidal and suicidal. The 5 deaths from beri-beri were the result of the epidemic outbreak of that disease during the last quarter of 1894. Excluding these seven deaths the mortality would be reduced from 105·4

per 1,000 to 85·0. At the close of 1895 only two lunatics were suffering from beri-beri.

Central Provinces.

In the two asylums of the Central Provinces (Nagpur and Jubbulpore) there were 381 lunatics under treatment during 1895, and of these 17 were fresh admissions. In the course of the year 34 patients were discharged as cured or otherwise, and 23 died, leaving 324 still under treatment at the commencement of 1896. The health of the patients was better than in 1894, and the admissions to hospital at Nagpur fell from 194 to 126, and at Jubbulpore from 122 to 103. Cholera was absent from both asylums. The chief cause of sickness was, as usual, malarial fever, from which there were 36 admissions at Nagpur, and 55 at Jubbulpore. At both asylums the mortality was lower as compared with the previous year. Of the total 23 deaths, Nagpur recorded 12, being in the ratio of 70·2 per 1,000 of average strength, against 13, or 80·6 in 1894. At Jubbulpore the deaths fell from 15 or 99·9 per 1,000 to 11, or 74·8. A dairy farm was started during the year at Nagpur Asylum with a fair amount of pecuniary success, for the venture cleared its expenses, and in future, now that the initial expenses have been cleared, it may be expected to yield a considerable profit, besides affording healthy and congenial employment to some of the inmates of the asylum.

Assam.

There is only one lunatic asylum in the province of Assam. This is situated in Tezpur, and the building is reported to be at present large enough for all demands on it. The total number of lunatics under treatment in the asylum during 1895 was 144, being a decrease of two on the number of the previous year. Of these 39 were fresh admissions. At the close of the year the patients in the asylum were reduced to 111, 26 of the total number having been discharged, and 7 died. Although the year was an unhealthy one in the district, there was less sickness in the asylum, and the mortality fell considerably. Among the 144 inmates 23 were admitted to hospital during the year, being in the ratio of 292·1 per 1,000 of average strength, as compared with 406·1 in 1894. The deaths fell from 28, or 264·4 per 1,000 in the previous year, to 7, or 65·9. Of these only two were received in good health, and one of them died of tetanus and the other of pneumonia.

Madras.

At the commencement of 1895 there were 623 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 221 fresh cases were admitted, bringing the total population up to 844, or 38 more than the number in the preceding year. In the course of 1895 there were 126 cases of discharge, and of these 93 were cured. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. The health of the insanes was not so good as in the previous year; the daily average sick rose from 105 to 123, and the deaths from 64, or 103·0 per 1,000 of average daily strength, to 110, or 182·5. Of the 110 deaths 94 occurred in the Madras Asylum, as compared with 56 in 1894. This great increase was due to the epidemic of cholera of the previous year, which extended to the first few weeks of the year under report, and resulted in 37 deaths. Excluding these, the deaths in this asylum are reduced to 57 or 129·4 per 1,000 of average daily strength. In Calicut there were 14 deaths, against 6 in the previous year, and of these 3 were received into the asylum in a moribund condition. Eighteen patients were admitted into this asylum suffering from tubercle of the lungs, of whom 13 died. The death-rate varied from 33·7 per 1,000 at Vizagapatam, and 135·4 at Calicut, to 213·6 at Madras.

Bombay.

The total population of the six lunatic asylums of the Bombay Presidency (Colaba, Ratnagiri, Poona, Dharwar, Ahmedabad, and Sir Cowasji Jehangir, Hyderabad) was 978, including 271 fresh admissions, against 1,000 in 1894. In the course of the year 191 patients were discharged, 80 of them as cured, and 68 died, leaving 719 under treatment at the close of the year. There was less sickness in the asylums than in 1894, the daily average sick having decreased from 48 to 45, and the death-rate fell from 138·8 per 1,000 of average strength to 94·7 Of the 68 deaths 12 were due to dysentery, 8 to epilepsy, 13 to chronic pneumonic phthisis, 8 each to epilepsy and Bright's disease, and 3 to cholera. The decrease of 33 deaths was shared in by all the asylums, but the largest decrease occurred at Poona, where the deaths fell from 32 or 336·8 per 1,000 to 18 or 210·5. The mortality at this asylum was chiefly attributable to the broken down condition of some of the lunatics on admission. All the three cholera deaths occurred at Poona, the other asylums were free from the disease.

Medical Schools.

The number of medical schools open in Bengal during 1893–94 was 12, against 9 in the previous year, the increase being due to the inclusion of three new schools in Calcutta, viz., the Electro-homœopathic School, the Bengal Eclectic Medical Institution, and the College of Physicians and Surgeons in Bengal. The Medical College, Calcutta, is affiliated to the University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the seven unaided schools (two at Dacca and five at Calcutta) follow their own standards for private practice. The total number of pupils attending the various medical schools in the province was 1,854, as compared with 1,784 in the previous year. Bengal.

The total strength of the Calcutta Medical College at the beginning of the session in 1895–96 was 511 (including 14 women), against 484 in the preceding year. As regards the examinations, 265 candidates (including seven women) were successful out of a total of 464 (including 12 women), the successes being at the rate of 57 per cent., as compared with 34 per cent. in 1894–95. The improvement in the percentage of success is considered satisfactory, "and is probably due to innovations introduced last "year, by which the students were made to see that they could be allowed to continue "their studies only by making good progress year by year." Of the 265 successful candidates, 152 (including five women) passed the Preliminary Scientific L.M.S. examination, 65 passed the first, and 28 the second L.M.S. examinations; 11 (including two women) passed the Preliminary Scientific M.B. examination; five passed the first and three the second M.B. examinations, and one as Doctor in Medicine; eight native dais passed in midwifery from the Eden Hospital, and received certificates of qualification, and 19 pupil nurses also passed as midwives.

The Campbell Medical School had 299 pupils (including 37 women) on its rolls during the session. Of this number 40 males and 4 women passed the final examination for the diploma.

At the Dacca Medical School there were 211 pupils on the rolls, 87 being in the third-year class, 71 in the second-year class, and 53 (including six women) in the first-year class. Sixty-one students of the third-year class passed the final examination, and 13 others, who failed in one subject only, were remanded for further examination after three months.

The Temple Medical School, Patna, had 159 students (including 8 women) on its rolls, a decrease of 26 compared with the previous year. At the final examination for the licence 52 candidates appeared, and 42 passed, including two women.

At the Cuttack Medical School there were altogether 163 pupils (including seven women). At the final examination for the licence 32 candidates appeared, and 26 passed, including one woman.

The number of pupils of the various classes of the Agra Medical School who attended the examination at the close of the year 1894–95 was 264 (including 51 women), as compared with 280 at the end of the preceding year. The results of the final examination of male students show that 50 out of 62 candidates passed. All but four of the 28 military students in this class passed, and 20 of the 23 civil students passed. Of the students in Class II., comprising second-year military and third year civil, private, and Rajputana pupils, one out of ten military pupils failed to pass the first half professional examination, and two out of 42 civil pupils. A rule rendering candidates ordinarily ineligible, unless recommended by the Director of Public Instruction, had, it is stated, the direct result of improving the status and qualifications of students entering the College. North-Western Provinces and Oudh.

As regards women students, the year's working shows that 49 out of the total of 51 were examined, and that 18 passed; three out of six in Class I., and 15 out of 22 in Class III. It is also reported that the social status and educational qualifications of the students annually admitted are steadily improving.

Notwithstanding the fact that Government no longer guarantees employment to the successful students in the Lahore Medical College, the numbers steadily increase year by year, and within the last seven years the class has nearly doubled. The total number of students at the Lahore Medical College and School during 1885–96 was 469, against 523 in the previous year. Of these 228 (including 2 women) were in the College Class, and 241 (including 6 women) were in the Medical Schools. The results of the year's examinations were on the whole favourable. Seventy-one candidates appeared at the first examination for the L.M.S. & M.B. degrees; of these one Punjab.

withdrew, and of the remainder 30 attained the pass standard compared with 16 out of 60 in 1894–95. At the final examination 10 out of 18 candidates passed, against 24 out of 36. One woman student passed the first examination for the L.M.S. diploma, and two were successful in the final examination. At the final examination for the Hospital Assistant Diploma, 89 candidates appeared, of whom 50 passed.

Madras. The total strength of the Madras Medical College during 1894–95 was 482, being a decrease of 97 on the attendance of the previous year. Of these 23 were women students, against 20 in 1894–95. In the Hospital Assistant Department, consisting of 218 pupils, 54 appeared for the College Diploma examination, of whom 52 passed, 11 being placed in the first class. The results of the several University examinations were again more favourable than in the previous year, 48 having passed out of 71 candidates entered, against 45 out of 98. In the College Department there were 34 (including one woman) regular students reading for the M.B. and C.M. degree, 44 (including two women) reading for the L.M.S. degree, and 16 casual students, two of whom belonged to the M.B., and 11 to the L.M.S. section. The percentage of passes to the total examined at the University examination was 67·6, against 44·7 in the previous year.

Government having decided to close the Board Medical School at Nellore, no admissions were made into the school during the year, there were, therefore, only five final year's students on the rolls. At the final examination for Hospital Assistant all the 22 candidates passed, with seven in the first-class. At the Prince of Wales' Medical School, Tanjore, there were again 22 pupils on the rolls, eight of whom were native Christians, seven Brahmans, and seven non-Brahman Hindus. Six candidates appeared for the Hospital Assistant examination, and passed.

Bombay. The attendance at the Grant Medical College, Bombay, increased from 250 in 1894 to 305 (including 19 women) in 1895. The results of the examinations were better than in the previous year. For the first University examination in medicine there were 86 candidates, of whom 52 qualified; and for the second examination in medicine 33 passed out of 76 candidates. For the final examination for the degree of L.M.S. there were 41 candidates, and of these only 12 passed, 2 in the first, and 10 in the second class.

The Government Medical School at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The number of students was 191, and of these 68 passed the final examination.

VII.—SANITATION.

In Calcutta further progress was made in the improvement of bustees, or clusters of native huts. The supply of filtered water was increased and the average daily consumption is now equal to 50·09 gallons per head of population for the town proper, and 20·11 gallons for the suburban area. In the course of the year the distribution pipes were extended about 3½ miles, bringing the total length up to 310½ miles, and the total number of premises connected had reached 26,312. The supply of unfiltered water was increased, the daily consumption per head of population being now equal to 13·43 gallons. The length of the unfiltered mains was extended by 1½ miles, bringing the total length of these mains up to a little over 75 miles. At the close of the year (1895–96) the total length of sewers was nearly 209 miles, and the number of premises connected with them was 29,140, of which 528 connexions were made during the year. The new drainage project for the municipality has at last passed out of the stage of preliminary discussion, and the Corporation were considering what course to take on the final conclusions of their professional advisers. Since the close of the year the project has received sanction and its execution commenced. Bengal.

The municipalities of the interior of Bengal spent Rx. 234,483 on sanitary works, an increase of Rx. 73,893 on the sum expended in 1894. The District and Local Boards spent Rx. 111,442 in improving towns and rural areas. No large works were undertaken by the District Boards, but a number of wells were sunk and tanks excavated. A further sum of Rx. 18,887, contributed by private individuals, was expended on sanitary works. The most important sanitary event of the year was the opening of the Howrah water-supply works, on which an additional sum of Rx. 51,343 had been expended. A further sum of Rx. 10,000 was devoted to the Arrah water works; the water is reported to be good, and the quantity consumed each day was 150,000 gallons. The Cossipur-Chitpur water-supply scheme and the drainage schemes for Patna and Muzaffarpur were completed. In many other towns and districts useful sanitary improvements were carried out during the year.

The Sanitary Board held seven meetings in the course of the year, when, among other matters, they discussed the improvement of the water supply of Darjeeling by the construction of settling tanks, the sewerage of the town of Dacca, and the provision of an unfiltered water supply for flushing drains and watering streets; schemes for the supply of drinking water to the towns of Gaya and Berhampore, which last was about to be taken in hand; the drainage and sewerage of Howrah and Krishnagar; and the chemical and bacteriological examination of water supplies. A number of minor sanitary works, including schemes for supplying filtered water to Faridpur and Pabna, and surveys for surface drainage in nine municipalities, were also dealt with by the Board during the year. Among the estimates considered by the Board was that for the extension of the Bhagalpur waterworks at a cost of Rx. 31,400, which received the sanction of Government, and the work was to be commenced as soon as possible.

In the North-Western Provinces and Oudh the municipalities spent over 37 per cent. of their income on water supply, conservancy, and drainage. Progress continued to be made in the sanitation of most of the large towns, and although there was still a lack of skilled local supervisors, expenditure was gradually being directed on more scientific lines. The Cawnpore and the Lucknow waterworks which were opened in the previous year supplied respectively 8·41 and 2·6 gallons per head of population daily, and in each case the quality was reported as satisfactory. The Meerut water supply project, which was sanctioned in the previous year, was completed at a cost of eight lakhs. Water-supply projects for the two large towns of Fyzabad and Bareilly were prepared during the year, but in both cases financial difficulties prevented further progress. At Agra fair progress was made with portions of the drainage and paving schemes, and at Benares 76 per cent. of the work on the main sewer was completed by the end of the year; while at Cawnpore the sewerage and drainage works in the Sadr Bazar were practically finished. A drainage and water-supply project for the town of Farukhabad was also under consideration, a sanitary survey having shown that the existing water supply was bad and the drainage imperfect. North-Western Provinces and Oudh.

The Sanitary Board held four meetings during the year, when attention was given to the question of closing all public and private burial grounds within municipal

limits; the Government order calling for a report on the best method of maintaining village sanitary records; the more pressing drainage works required in the Meerut and Agra divisions; the complete sanitation of places of pilgrimage; and the supply of pure water to pilgrims at the Magh Mela at Allahabad. The Sanitary Board were instructed to prepare a manual relating to the disposal of night-soil at municipal centres, and in consultation with the local authorities to give effect to a series of rules dealing with such measures of rural sanitation as are reasonably within the competence of village communities.

Punjab. In the Punjab the municipal towns spent 22 per cent. of their income on sanitary work. A sum of Rx. 13,943 was realised from the sale of manure and town sweepings in the various municipal towns in the course of the year, as compared with Rx. 12,364 from this source in 1894. During the year the water-supply schemes for Umballa City and Delhi were completed; those for the towns of Pind Dadan Khan and Haripur were in progress; and many others were under consideration. The drainage schemes for Ludhiana, Gujranwala, and Peshawar City were finished; while those for Delhi and Lahore, and the construction of the main outfall sewer at Jhelum, were still in progress. In Gurdaspur district a few drainage works of importance have been made and these, it is reported, will improve the drainage of the country very considerably. A number of works of public utility were also constructed during the year by private individuals at their own expense to serve sanitary purposes.

Four meetings of the Sanitary Board were held during the year, when the following matters were discussed:—Rules to be observed at the more important fairs in the province; causes of the unhealthiness of certain tracts in the Umballa district and Kalsia State; the combined drainage scheme for the city and cantonment of Rawalpindi; the excessive fever death-rate in the province due to water-logging; and the severe outbreak of small-pox in the City of Multan.

Burma. The towns and districts of Burma spent over 36 per cent. of their income on the work of sanitation. No new work of any magnitude was begun; but several large projects were under consideration, the extension of the Rangoon water supply and the establishment of waterworks in the towns of Mandalay and Moulmein being the most important. The population of Rangoon is said to be fast outrunning the present water supply and an elaborate project has been prepared for bringing an adequate supply from Hlawga, 17 miles from the town. The estimated cost of the project is put down at 25 to 30 lakhs, but before burdening the town with such a heavy expenditure the municipal authorities decided to ascertain beyond question whether a sufficiently bountiful supply could not be obtained by sinking tube wells. Experiments were in progress. The Shone and Ault system of conservancy was being gradually extended in Rangoon City, and steady progress was being made with the reclamation of the east of the town. At Prome the filter gallery connected with the pumping station, which had been abandoned for the past nine years, was put into working order, and the majority of the inhabitants of the town are now supplied with water from the hydrants. On several occasions the water was subjected to analysis and pronounced to be good.

The work of the Sanitary Board continued to be restricted to the provision of suitable sanitary maps of the larger towns in Lower Burma. The maps required have now been prepared and steps were being taken to carry out the survey.

Central Provinces. The municipalities of the Central Provinces devoted 16½ per cent. of their income to sanitary purposes. The larger works undertaken or in progress were as usual all in connexion with water supply; drainage works, though urgently needed in some localities, appear to be beyond the means of any municipality. The Jubbulpore waterworks were further extended during the year. A new scheme for supplying Wardha with water at a total cost of Rx. 20,706 was submitted, and the foundation stone of the work was laid by the Chief Commissioner in December 1895. In addition waterworks were in progress at Harda and Khandwa, and a similar scheme for Hoshangabad was about to be commenced. Several minor drainage schemes were carried out during the year. Regarding village sanitation, Dr. Newman says the most rudimentary attempts at sanitation are very rarely found. "As in the towns, so in "the country, the people, with a few extraordinary exceptions, appear not to "understand in the least the danger of neglecting sanitary precautions, and except "where the Sanitation Act is in force, or an official appears to insist on improvement "and supply the necessary funds, nothing whatever is done to prevent filth or remove

" fæcal accumulations from the vicinity of the houses or surface of the streets, to " repair the wells and tanks, or to save them from the foulest pollution."

The Sanitary Board met in each division of the province during the year. At the first annual general meeting held at Nagpur in August statements were presented showing that since the institution of the Board works had been completed at a cost of Rx. 19,264, while those under construction and others to be carried out during the following year would amount to Rx. 5,143.

Excluding the towns of Sunamganj, Karimganj, and Maulvi bazar, in which allowances for sanitary purposes are made by the Local Boards, the municipalities, stations, unions, and towns in Assam spent 44·13 per cent. of their income on sanitary improvements, irrespective of roads and bridges. No sanitary work of special importance was completed, but considerable improvements were effected in the water-works of Gauhati and Shillong, and the first of a series of wells to supply the town of Sylhet with drinking water was completed. A complete drainage scheme for Gauhati was sanctioned and the work was commenced before the close of the year. A similar scheme for Barpeta was under consideration. Steady improvement was made in works for improving the sanitation of villages especially in the way of providing a pure water supply. The question of introducing village sanitary inspection books was under the consideration of the Chief Commissioner, and orders have since been issued bringing these books into use in selected villages from the 1st August 1896. Assam.

The Sanitary Board met twice during the year and were chiefly occupied with the preparation of rules for the sanitation of villages and in drafting a Village Sanitation Regulation.

In improving the sanitation of Madras city several new drains were constructed and old ones repaired during the year. The water supply was extended and increased, but the quality, as in previous years, was pronounced to be bad on chemical examination. " Considering that the supply is unfiltered," the President of the Municipality writes: " This is not much to be wondered at; but, as stated last year, the cost of any " efficient scheme hitherto proposed for filtering the water supply of Madras would " be beyond the means of the municipality." The question of carrying out a comprehensive scheme for the drainage of the whole town was still under the consideration of a committee. Government have granted a sum of $3\frac{1}{2}$ lakhs towards the drainage of the city, and it was expected that the work would shortly be commenced. Madras.

The other municipalities of Madras Presidency allotted 56 per cent. of their income for sanitary purposes, and the District Boards about 9 per cent. Conservancy appears to receive considerably more attention than water supply, judged by the expenditure on each. The Sanitary Commissioner says: " It is far more difficult to get a " municipality to act in the matter of protection of water supply than the disposal " of sewage; sewage is a nuisance that all are glad to get rid of, and so long as the " expenditure contemplated is not very great, petty schemes for its removal are " readily voted for; but to persuade a council that water they have used day by day " for many years on end—albeit that their less lucky contemporaries who also used it " died prematurely—is unfit for use, is not so easy a task." During the year the Sanitary Engineering Department completed surveys for water supply or drainage, or for both, for three municipalities. Two water-supply schemes were submitted to Government, of which one was sanctioned for execution, and four were under the consideration of the Sanitary Board. Six projects were under execution. Of these the Adoni and Tanjore works were completed, and very little remained to be done at Trichinopoly, while fair progress was made with the scheme for the water supply of Dindigul. The improvement of the drainage at Ootacamund received attention and proposals were made as regards an alternative scheme for the water supply of Coonoor. One hundred and fifty-one plans and 120 estimates for sanitary works of the aggregate value of Rx. 26,934 were scrutinised during the year, as compared with 100 plans and 102 estimates of the aggregate value of Rx. 10,470 in 1894.

The Sanitary Board was reconstituted at the beginning of 1895, and amongst the subjects which engaged their attention during the year were the improvement of the water supply of Marlimund at Ootacamund, the drainage of Ootacamund, and filling in the upper portion of the Ootacamund lake, the water supply of Coonoor, sanitary improvements of the town of Cuddapah, schemes for the water supply of Tuticorin, improvement of drainage of Tadpatri, and the improvement of the water supply of Masulipatam.

Bombay. In Bombay city the works in connexion with the sewerage of Colaba on the Shone system were practically completed towards the end of the year at a cost of over 7½ lakhs and in several other divisions of the city drainage and sewerage works were either completed or in progress. The water supply from the Tansa, Vehar, and Tulsi lakes continued to be adequate. During the year 522 new connexions were made and 243 services disconnected on account of buildings demolished and other reasons. The net increase was, therefore, 279, bringing the total up to 19,445.

In Bombay Presidency the municipalities, exclusive of Bombay city, allotted 45·28 per cent. of their income for sanitary purposes. As usual, however, the amount actually expended fell short of the allotment, only Rx. 182,196, or 84·71 per cent., having been spent during the year. Of this sum the outlay on conservancy amounted to Rx. 86,922, on water supplies Rx. 49,654, and on improvement of town sites Rx. 21,598. The District Boards assigned Rx. 78,921 of their income to sanitary works, but only Rx. 51,670, or 65½ per cent., were actually spent, chiefly on improvement of water supply, including cleansing, repairing, and construction of wells and tanks, on which a sum of Rx. 47,620 was expended.

In the course of the year the Sanitary Board gave advice concerning a large number of projects, among which were improvements to the waterworks of Dakor, Alandi, and Kirki, and a water supply scheme for Yeola in Nasik district, the experimental drainage scheme for Ahmedabad, the drainage and sewage of Parel, a draining project for the town of Dhulia, and the question of the house connexions of the Government buildings with the Colaba sewerage system.

Berar. The municipalities of Berar spent 42 per cent. of their income on sanitary improvements. No new works of any magnitude were undertaken during the year, but satisfactory progress was made with the drainage works at Shegaon, and the question of draining Amraoti was under consideration. At Akola steps were being taken for the drainage of the town, and at Akot and Ellichpur considerable proportions of the funds were expended in the same direction.

The District Sanitary Board met once at each of the six head-quarter stations to examine the improvements effected on the recommendations of the provincial Sanitary Commissioner since 1888, the year in which a systematic sanitary survey was started in Berar. In many instances the recommendations were found to have been carried out, but want of funds greatly impeded progress. The question of a sanitary law for the improvement of village sanitation was under consideration.

India Office,
27th October 1897.

W. T. Ronson.

ABSTRACTS

OF

SANITARY AND OTHER REPORTS

FOR

1895.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1895.

(Surgeon-Major General J. Cleghorn, M.D.)

European Troops.

Revision of tables.

In accordance with the instructions and suggestions of the Army Sanitary Commission in their review of the report for 1893, the tables for 1895 appear in a new and simpler form. The recasting has been carried out by re-arrangement and by avoidance of repetition; and the result is that, though the number of tables has been reduced by exactly one-half, yet not only has nothing of importance been omitted, but a considerable amount of fresh information has been furnished. The general plan of the new tables can be easily grasped by looking over the table of contents.

Sickness and mortality in 1895.

Judging from the admission and death-rates, the health of the European army of India was better in 1895 than in the preceding year. The progressive increase in the constantly sick-rate is probably connected with the progressive increase in the number of cases of enteric fever and of venereal diseases, and with the increase since 1890 of influenzal respiratory diseases; that is, with the increase of diseases which keep men long in hospital. The average duration of a case of enteric fever was 52 days and that of a case of venereal disease 31 days.

European Troops in India.

Year.	Strength.	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	Total Loss.
1870–79 - - - -	57,742	1,475	60	19·34	43	62
1881–90* - - - -	61,399	1,471	73	14·24	27	42
1894 - - - -	71,082	1,508	92	16·07	25	42
1895 - - - - -	71,031	1,462	94	15·26	23	39

* Including troops in Afghanistan during 1881.

The chief causes of admission were venereal diseases and ague. Among the diseases with increased admission-rates were influenza, enteric fever, remittent fever, and dysentery. On the other hand, the admission-rates from cholera and ague were lessened. Venereal diseases caused 36 per cent. of the total sickness, and ague 23 per cent.

The chief causes of death were enteric fever, hepatic abscess, and dysentery. Among the diseases with increased mortality were dysentery and enteric fever. On the other hand, the mortality from cholera and respiratory diseases was lessened. Enteric fever caused 44 per cent. of the total deaths.

The chief causes of invaliding were, in order, syphilis and gonorrhœa, malarial fevers, debility, tubercle of the lungs, injuries, valvular disease of the heart, rheumatism, mental affections, dysentery, hepatitis, and palpitation.

It has been stated that the mortality per 1,000 of European soldiers in India was for the period 1800–30, 84·60; for the period 1830–56, 56·70; for the period 1869–78,

19·30; for the period 1879–88, 16·02. To this it may be added that the ratio for the period 1889–94 was 15·91.

At page 55 there is a table showing for certain diseases for India the mortality for three periods included in 1870–95, 1870 being the earliest year for which the statistics of India as a whole are available. But, as it is of interest to have also older statistics for comparison, the following table has been prepared for the Bengal Presidency from the earliest available year, 1858, up to 1894, the last year in which the Bengal Presidency existed as a separate command.

The year 1858 being still subject to the disturbing influence of the mutiny, it has been kept separate. The next period was chosen because the late Dr. Bryden stated that from 1858 to 1863 no new regiment was added to the garrison of India. In the year 1870 the short service system was inaugurated in England, and is presumed to have begun to affect India seriously from 1877.

In this office there is no record of enteric fever before 1870, but in the army medical blue book it appears from 1861. The ratios given in the second and third periods in the following table have been derived from the blue books; but no deduction has been made from the other fevers, as it could not be discovered from which the deduction should be made.

The high constantly sick-rate in the fifth period is probably due to the causes mentioned in the first paragraph.

Leaving aside the cases in which increase or decrease has been fluctuating, it may be said that in the fifth period there was increased admission from enteric fever, ague, alcoholism, and venereal diseases; increased death from enteric fever and respiratory diseases; increased invaliding from mental affections, diseases of the organs of the special sense, and injuries; and diminished admission, death, and invaliding ratios under all the remaining and most numerous headings.

The increase of enteric fever and venereal disease is evidently connected with the short service system. The increase in ague may be due to exposure on active service, and to the addition to the empire of large malarious regions on the north-western and eastern frontiers. The increase in mortality from respiratory diseases is pretty certainly due to the epidemic influenza, which has not left the country since it first appeared in 1890. The decrease in cholera, scurvy, and some other diseases may be put down to improved hygiene. The decrease in remittent and in simple continued fever is probably mostly due to change in diagnosis, and transfer to the head of enteric fever. Hepatitis was shown by Dr. Bryden to be a disease of degeneration, a disease of the old soldier. Its diminution appears, therefore, to be a good result of the short service system.

* Including diarrhœa.

† Including apoplexy up to 1870.

The total fever mortalities of the four forms of fever given in the table are, for the periods given, respectively 18·57, 4·57, 3·85, 3·28, and 5·80. The total fever mortality has therefore risen since the Indian army came under the short service system. But, nevertheless, the total mortality from all causes has been reduced.

In the period 1859–63 the maximum death-rate was 44·77, the minimum 22·49, and the ratios of two of the years were above the period ratio; in 1864–69 the maximum death-rate was 42·89, the minimum 20·11, and two of the years had ratios above the period ratio; in 1870–76 the maximum death-rate was 27·45, the minimum 14·62, and two of the years had ratios above the period ratio; in 1877–94 the maximum death-rate was 44·15, the minimum 11·21, and five of the years had ratios above the period ratio. Very high ratios were therefore exceptional in all the periods. The two highest ratios in the last period were those of 1879 and 1880, the years of the Afghan war. The death-rate was at its lowest from 1882 to 1885; cholera, fevers, respiratory diseases, and bowel complaints all giving low mortalities. Since 1885 the death-rates have been higher, the maximum 19·81 and the minimum 14·35. The increase is probably connected with the conquest and occupation of fresh territories on the eastern and north-western frontiers. Some of the years with high ratios, such as 1891, 1892, and 1894, were also distinguished by prevalence of cholera. It is usual for the Bengal-Punjab death-rate to be higher than that of Madras or Bombay.

The ratios of the four commands are shown in the following table. Bengal had the highest mortality from cholera, dysentery, and hepatic abscess; the Punjab the

highest from enteric fever, malarial fevers, heatstroke, and pneumonia; Madras the lowest from enteric fever and pneumonia; Bombay the lowest from dysentry. The percentage of enteric fever in total deaths was greatest in the Punjab, and the percentage of hepatic abscess in Madras. The total death-rate of the Punjab, which was the highest, was more than double that of Madras, which was the lowest.

The following table gives vital statistics of the European troops in Burma as a whole:—

Period.	Strength.	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths from		
				Cholera.	Other Causes.	Total.
1890	4,712	1,743	102	—	20·80	20·80
1891	4,623	1,589	92	2·38	17·74	20·12
1892	4,316	1,491	91	—	14·83	14·83
1893	3,928	1,461	96	·25	12·73	12·98
1894	3,940	1,465	93	·25	9·39	9·64
1895	4,045	1,410	96	·99	8·41	9·39

Burma in 1895 was distinguished by the prevalence of influenza and hepatitis,

The following table shows that, judging by the constantly sick rate, Groups II., XII*b*., and V. were the most unhealthy for the decennium, and XII*a*. the most healthy. It also shows that the 1895 constantly sick rate of every group except XI. was higher than its corresponding decennial ratio, and that the rise was greatest in the case of IX., VIII., and XII*a*. But the constantly sick ratios of six groups were better than in the previous year:— Geographical groups.

		Ratio per 1,000 of Strength.												
		I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII*a*.	XII*b*.	
		Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalayan.	Indus Valley and North Rajputana.	South-Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Depôts.	India.
1882–91	Constantly sick	74·6	91·4	82·8	83·0	81·6	79·4	78·8	69·8	72·0	75·7	65·1	90·6	74·0

1894	Constantly sick	97·5	94·8	89·9	105·7	99·3	96·2	113·2	86·4	75·2	80·5	84·3	90·5	91·6
	Death—Cholera	—	·38	·45	18·22	·14	—	—	·20	—	—	—	—	2·10
	Death—Enteric fever	·88	1·89	3·57	6·38	7·63	7·33	7·39	5·53	1·17	3·55	6·28	8·22	5·75
1895	Constantly sick	86·4	102·4	96·9	105·4	94·1	87·6	104·8	97·2	83·3	71·5	90·6	105·0	93·7
	Death—Cholera	—	1·51	·88	2·12	·14	—	·63	·52	—	—	—	—	·45
	Death—Enteric fever	4·04	1·51	6·16	7·36	6·61	8·18	7·40	5·16	2·56	1·32	5·36	3·90	6·72

Gangetic Plain had the highest constantly sick rate; Indus Valley the highest admission and death rates; and Southern India the lowest constantly sick, admission, and death rates; Burma Coast had the highest admission rates from influenza, and the lowest from remittent fever, simple continued fever, tubercle of the lungs, respiratory diseases other than pneumonia, and diarrhœa; Burma Inland the highest from hepatitis, and the lowest from pneumonia and abscess of the liver; Gangetic Plain the highest from cholera, enteric fever, and venereal diseases; Upper Sub-Himalayan the lowest from hepatitis; Indus Valley the highest from ague, pneumonia, other respiratory diseases, and diarrhœa; Western Coast the highest from simple continued fever, and the lowest from ague and dysentery.

In the decennium also the Gangetic Plain had the highest admission ratios from cholera and enteric fever.

The percentage of enteric fever to total admissions in 1895 was greatest in the Gangetic Plain; of hepatic abscess and venereal diseases in Burma Coast; of remittent fever and dysentery in Bengal-Orissa; of ague, pneumonia, and other respiratory diseases in the Indus Valley; of simple continued fever in Western Coast.

The highest ratios among the large garrisons with a strength of over 1,000 were those of Lucknow, Peshawar, Chakrata, and Aden, and, except in the case of Lucknow, these ratios were higher than those of the preceding year. Stations.

Sickness and mortality having been studied in their relation to India, to commands, to geographical groups, to stations, and to regiments, it will be convenient here to discuss the statistics of some of the chief diseases. After a pause of two months influenza began again in January 1895, reached its maximum in April, sank gradually till August, and rose again gradually till December. The following table shows the increase in 1895 over 1894. It also shows the fluctuations of the disease since 1890, the first epidemic year:— Principal diseases: Influenza.

Admissions from Influenza.

Period.	India.													
	Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Total.	Per 1,000 of strength.
1890	—	3	473	1,451	248	69	13	2	3	—	—	1	2,263	33·4
1891	1	—	1	16	77	91	112	29	20	2	2	21	372	5·5
1892	113	53	354	241	57	4	32	8	—	—	—	—	862	12·7
1893	1	—	—	15	4	—	—	—	—	—	—	1	21	·3
1894	7	9	12	70	101	30	7	7	—	2	—	—	245	3·4
1895	14	7	52	156	66	35	17	1	5	13	23	165	554	7·8
Total	136	72	892	1,949	553	229	181	47	28	17	25	188	4,317	—

The actual maximum of the individual years of the six occurred in various different months, but over the six year period as a whole the greatest number of cases occurred in March, April, and May, the hot dry months before the rains, and the smallest number in the four months August to November. Geographical Groups I., V., VI., VIII., XI., and XII*a*. were attacked both in 1895 and in 1894; Groups II., VII., IX., and XII*b*. in 1895 only, while Groups IV. and X. were spared in both years. 23 stations were attacked in 1895 against 20, nine of them suffering in both years. Among stations Rangoon and Sialkot had the greatest number of cases. The outbreak at Sialkot was a very compact one, confined to one month, while at Rangoon cases occurred in eight months of the year. The average number of men constantly sick with influenza was 16 and the average duration of a case 10 days. The returns deal, of course, only with those cases which were admitted into hospital, but there were mild cases not admitted.

Cholera.

The amount of cholera was much less than in the previous year, and very low, as may be seen from the following table:—

Cholera.

Period.	India.			
	Admissions.		Deaths.	
	Number.	Per 1,000 of Strength.	Number.	Per 1,000 of Strength.
1870–79	2,697	4·7	1,864	3·22
1881–90	1,320	2·1	899	1·46
1894	209	2·9	149	2·10
1895	44	·6	32	·45

The disease was at its maximum in May, and was epidemic only at Fyzabad and Secunderabad.

Small-pox.

The admission rate rose slightly, the death-rate fell slightly. The death-rate was only one-third of the decennial death-rate. The greatest number of cases at any one station was four at Bangalore, and three each at Saugor and Rawalpindi.

Fevers.

Ague gave rise to about 23 per cent. of the admissions from all causes. The most noteworthy feature of the monsoon rains of 1895 was their general deficiency over the whole of India to the north of latitude 18°. With this may be connected the fact that the year was decidedly less malarious than its predecessor:—

Period.	Intermittent Fever.		Remittent Fever.		Simple continued Fever.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–91	330	·15	8	·53	73	·05
1894	412	·18	9	·37	20	·01
1895	336	·25	13	·30	22	·04

As shown above, there was a considerable rise in the admission rate from remittent fever. This was partly due to the occurrence of a large number of cases in the Chitral Field Force; but there was also an enormous increase in the Bengal-Orissa group, the admission ratio having risen from 15·2 to 65·5. The increase occurred at Calcutta and Dum-Dum. The medical officer of the former station says:—"The "increase is partly to be accounted for as occurring in a regiment, the 1st Shropshire "Light Infanty, which had suffered a good deal from malaria in Hong-Kong previous "to coming here, and partly to a general increase of these fevers in this town from "some cause which could not be accounted for."

Enteric fever.

It must be confessed that increased experience has not on the whole made the bacteriological investigation of disease easier. The progress of knowledge has revealed how little is known; the characters of many bacteria do not appear so sharply defined as at first, and identification has become a complicated and laborious process. This is specially true as regards the examination of water for specific microbes, and not least so in the case of the enteric bacillus. The difficulty is so great that men like Duclaux, Kruse, Buchanan, Gaertner, Löffler, and others have said that whether a water is safe or not cannot be found out by chemical or bacteriological analysis in a laboratory, without also going to the spot and examining into the local possibilities of contamination. If the bacteriologist has to do, on the one hand, with a cultivation of the enteric bacillus made from the spleen of a patient dead of enteric fever, and, on the other, with a cultivation of *bacillus coli* derived from healthy fæces, he finds, on employing a complete series of the accepted tests, that the two are distinguished from each other by certain well-defined characters. But when the material to be analysed is a sample of suspected water, great difficulties have to be overcome. The first difficulty is that the analyst can never be sure that his negative results are correct, even if he deals with litres instead of with drops, because of the probably sparse diffusion of the bacilli in a relatively vast bulk of water. The necessity of using large quantities of the water, and of caution in proclaiming negative results, has lately been specially emphasized by Klein, who has also remarked that the search is like looking for a needle in a rick of hay. The second difficulty is the presence in the water, often in enormous numbers, of the ordinary water-bacteria, especially of those which liquefy gelatine. No primary process has yet been discovered which will separate the enteric bacillus *alone* from these. The most frequently employed processes, such as that of Parietti, can only separate the enteric bacillus, the *bacillus coli*, and certain intermediate forms from the more ordinary microbial inhabitants, leaving to another stage the separation of the enteric bacillus from those resembling it. The third difficulty is the extremely frequent occurrence of the *bacillus coli*, in water, the family likeness between the *bacillus coli* and the enteric bacillus, and the existence of forms intermediate between the two. As an example of the kind of difficulty caused by these intermediate forms the following may be adduced:—Wernicke and Bussenius examined the typhoid like bacilli from the wells of a farm, where cases of enteric fever had occurred. Only after careful testing they got a microbe with the greatest likeness to the enteric bacillus, except in its behaviour to sugar and to milk. But, as they considered that they had sometimes observed slight gas-production in cultures of the enteric bacillus in saccharine media, they were inclined to regard this bacillus found in the water as an enteric bacillus rendered abnormal by continued saprophytic existence in water. This conclusion comes near certain views of Hankin regarding the degeneration of specific microbes in water. Hankin is supported by McWeeney in the opinion that these abnormal forms are at least companions of the enteric bacillus in water.

"*Hankin.*—Like other authors, I have found that there exists a whole series of intermediate gradations between what I believe to be the typical enteric microbe and the bacillus coli communis. Practically this fact does not present such difficulties in diagnosis as might be expected, as very generally when these are detected the enteric microbe can also be found if sufficient care be exercised. It is clear that microbes allied in their cultural characters to that of enteric fever are found so rarely in the absence of the typical enteric microbe, as not greatly to detract from the value of the test.

"*McWeeney.*—To these conclusions I wish to add one other, which is founded upon a large number of biological investigations made by me during the last few years upon water suspected of being the vehicle of typhoid germs, namely, that these pseudo typhoid or coliform organisms occur regularly and abundantly in water to which attaches the suspicion of causing typhoid fever, very seldom and in small numbers in water which is beyond the possibility of sewage contamination."

Possibly a more extended application of the serum test of Pfeiffer may clear up some of the difficulties caused by the presence of these intermediate forms.

"*Pfeiffer.*—In the serum of enteric convalescents there are present substances which in small quantities kill and dissolve living enteric bacilli in the bodies of guinea-pigs. The action of the bactericidal substances of the serum is specific; it affects only enteric bacilli, not enteric-like bacilli. It can therefore be used for distinguishing the true enteric bacillus from those related to it or like it. The demonstration of the specific bactericidal substances of the serum of enteric convalescents is a new proof that the typhoid bacillus alone plays the etiological rôle in enteric fever and is specific."

Pfeiffer's statements have been confirmed by other competent observers. This serum test of Pfeiffer's seems, then, to be at present the only known certain test for the enteric bacillus; but its application requires judgment as well as skill. The method is not only used for the differentiation of the enteric bacillus in the laboratory, but has been employed with success in Paris and elsewhere for the diagnosis of enteric fever, bacilli from an authentic culture being treated with a few drops of the patient's serum. Klein has lately stated that the method is more certain in the test-tube than in the body. Elsner's new culture medium (acid potato-juice gelatine with potassium iodide) has rendered the detection of the enteric bacillus much easier than before. This medium eliminates the ordinary water saprophytes, and at the same time differentiates the enteric bacillus from the *bacillus coli* by the much slower rate of growth in it of the former. It has been applied with great success to the detection of the bacillus in the stools, and Elsner hopes by its aid to be able to study the occurrence of the enteric bacillus in nature apart from cases of enteric fever. Separation by Elsner's medium and confirmation by Pfeiffer's serum constitute the most perfect process yet discovered for the purpose. Petruschky's litmus whey process confirmed by Pfeiffer's serum seems to be also a very satisfactory method. For water the best procedure seems to be:—(1.) Passing a considerable quantity of the water through a Pasteur filter, and using the deposit on the cylinders for the analysis; (2.) Elimination of ordinary saprophytes by Parietti's method, or, better still,* the omission of this second stage, and, with the use of Elsner's medium, passing direct to (3.) The making and examination of plate and streak cultivations; (4.) The differentiation of the enteric bacillus from enteric-like forms by the acid-production test (Petruschky's litmus whey, litmus agar), by the milk-coagulation test, by the gas-production test, by the indol-production test, by the classical potato test, by Pfeiffer's serum test, and by other tests the constant addition to the number of which of itself sufficiently indicates how little satisfied observers are with those they already possess. The microscopical characters are not much trusted to now-a-days, though they should be used as contributary confirmations. In all European laboratories also standard cultivations of the enteric bacillus from the spleen and of the *bacillus coli* from fæces are kept up for purposes of comparison. When a doubtful microbe is found in the course of a research, its behaviour to the usual tests is compared with that of the standard to the same. Mr. Hankin in India has not often been able to use the filter method in the first stage, as the samples sent to him have been too small. For the second stage he uses a modification of Parietti's process; for the third, zig-zag cultures on agar in tubes; for the fourth, litmus agar, potato, milk, and the microscope. It will be noticed that some of the tests given above are not used by Mr. Hankin; but his method as it stands is already so complicated and laborious that it is a matter for astonishment that he should be able to carry out the process thoroughly in so many cases, considering the amount of other work, bacteriological and chemical, that has to be got through at Agra. There ought to be half-a-dozen expert bacteriologists instead of one for the work as it is at present, and the work will increase. An augmentation of the number of bacteriologists would also be advantageous in the way of check; it is not good for a bacteriologist to be alone, with no one to contradict him. Bacteriologists in Europe appear to distrust each other in the matter of the detection of the enteric bacillus in water, unless the most rigorous proof be forthcoming; and in their own work they do not always arrive at more than a probability. Mr. Hankin says himself that his method was more or less tentative, but appeals to results in the improvement of health of stations, as shown by answers of medical officers to a circular of his, as justifying his diagnoses. But, unfortunately, a scrutiny of these "results" showed that their accuracy left a great deal to be desired; and judgment must remain suspended.

It is in view of the great and increasing importance of enteric fever as a disease of the British troops in India, and of the prominence which has been given to the alleged detection of the specific bacillus in the food and water supplies of the soldier,

* Lösener and others altogether distrust Parietti's method, and those like it, preferring to add the phenol directly to the gelatine or agar from which the plate cultivations are to be made.

that it has seemed necessary to give the above brief account of the latest views of experts concerning this bacillus and its relation to enteric fever. Medical officers in India have not always the opportunity of consulting the works of bacteriological specialists; and a *résumé* of what is at present known and believed about the subject will be, no doubt, of interest and of practical benefit to them.

It is too generally assumed that the detection of the bacillus is a very simple matter, and that the connexion between the presence of the bacillus and the occurrence of enteric fever is unquestioned and unquestionable. These beliefs are, however, not in accordance with the opinions expressed in some of the latest English and German writings on the subject, published in 1896 :—

"*Kruse.*—The differential diagnosis of the typhoid bacilli, which was formerly quite simple, has now become very complicated, since the knowledge of the related bacteria of the colon-group has been attained. No single character is peculiar to the typhoid bacillus: only by the presence of all its characters in their totality can it be differentiated. . . . . A certain variability, however, attaches to some of these characters.

"*Pfeiffer.*—Notwithstanding these really great difficulties, cholera bacilli have already been demonstrated with certainty in a whole series of cases in well, river, and pipe water. On the other hand, the statements hitherto made regarding the finding of enteric bacilli in water are to be criticised very sceptically.

"*Dreschfeld.*—In conducting bacteriological examination of water, it must be borne in mind that a number of bacilli may occur in water which closely resemble the typhoid bacillus both in appearance, in the character of the colonies, and even in some of the re-actions; so that it becomes necessary to use every one of the differential tests given above; indeed, in the present state of our knowledge, even if the organism do present the various test re-actions, we can then only say that it is like the typhoid bacillus.

"*Crookshank.*—Whether this bacillus is really peculiar to typhoid is much disputed. Bacilli very closely resembling it, if not actually identical, have been found under other conditions. These pseudo-typhoid bacilli are regarded by some bacteriologists as varieties resulting from the different environment afforded by a saprophytic existence. . . . . Sufficient has been said to show that bacteriological reports in which it is stated that the typhoid fever bacillus has been found in water causing typhoid epidemics must be accepted with great reserve; and, further, no one is justified in stating that the typhoid fever bacillus is undoubtedly the cause of typhoid fever."

Readers of the above quotations who wish to realise how widely felt is the difficulty of detecting the enteric bacillus in water, and how common the *bacillus coli* is in water and elsewhere, may do so by a perusal of the papers to which references (not reprinted) are given at the end of this section.

Klein has lately shown that the enteric bacillus can live longer in water and in sewage than had, from various experiments, been supposed. Like others he found that waters of different sources or of different treatment (sterilised, boiled, filtered, &c.) are apt to have different effects upon the bacillus. If the enteric bacillus gains access to a pure water, the length of its life therein appears to be determined by the amount of organic matter present in the water or carried into it along with the bacilli. Hankin also records the following :—

"My assistant, Dr. Gadially, has recently noticed that when a particular microbe is present in specimens of water or milk sent to my laboratory, the enteric microbe is never met with. I propose to call this microbe the 'micrococcus Gadiallii.' We have isolated it, and found that it has the power of destroying the enteric microbe in water, bouillon and milk. Possibly the presence of this or similar microbes in bazar wells is one reason why they are so rarely infected with enteric. Drinking their water may produce dysentery, malaria, cholera, or liver abscess, but it would appear to be the way to avoid enteric."

Other experimenters have also occupied themselves with the behaviour of the enteric bacillus in different waters.

Mr. Hankin has brought to the notice of regimental authorities and others the desirability of keeping aërated waters for some time before use. The following are very interesting and important remarks by G. C. Frankland on the same subject :—

"As regards typhoid infected water we cannot resort with any degree of security to carbonated waters, unless we have proof that the manufactured article has been stored for at least a fortnight before use. Slater observed typhoid bacilli alive in ordinary aerated water as long as 11 days; and both Abba and Hochstetter record a vitality of five days. In some cases, however, they seem to disappear much more rapidly, and doubtless a great deal depends upon the initial vital condition of the particular cultivation of typhoid bacilli employed. Here again Dr. Abba finds in *sterilised* alkalised aërated water that the persistence of the typhoid bacillus is superior to that observed in similar waters not deprived of their bacterial life. (The coli behaves in the same way, but is more hardy.) It would appear reasonable, therefore, to make a practice of storing such waters before distribution, a measure recommended many years ago by Duclaux, and which, in the absence of

preliminary precautions, such as the removal of all bacteria present by boiling, distillation, or efficient filtration, would appear to be a measure of great hygienic importance."

Dempster, in the course of an inquiry into the influence of different soils, found that in dry earth the enteric bacillus soon perished, but that the presence of moisture enabled it to live long.

Diffuse daylight appears to have little influence on the bacillus, and the effect of direct sunlight is dependent on the simultaneous presence or absence of air; in the former case the bacillus quickly perishes.

Lösener found that in unburied bodies the enteric bacillus lived three or four days, but in buried bodies they could be found up to 96 days.

In a fœtus aborted in the course of its mother's fever, Freund and Levy found the enteric bacillus in the spleen of the fœtus and in the placental blood; while the intestinal mucous membrane, "as usual in intrauterine typhoid," was normal.

Thiemich and Teissier found the bacillus in the blood of the rose spots and of veins; and in four of the cases the diagnosis was confirmed by *post-mortem* examination.

As to the enteric bacillus and the coli in the urine there are some new observations. Judalewitch says that the enteric bacillus can pass in the urine, and this is not dependent on parenchymatous nephritis, in the third week, and some time after convalescence; and that the disinfection of the urine may in some cases restrain the spread of the disease. Baart de la Faille says that the presence of the enteric bacillus in the urine is almost invariably associated with albuminuria, and frequently with acute nephritis. In 27 cases he found the enteric bacillus four times, the *bacillus coli* four times, and other bacteria in the other cases. He thinks the specimens of the enteric bacillus he found were real; but acknowledges that the methods employed may possibly have brought forward a variety of the bacillus closely resembling the enteric bacillus. Kruse states that the analyst has the prospect of finding the enteric bacillus in the urine in about half the cases examined.

Pfuhl in the course of a certain investigation found reason to believe that the disease may have been spread in barracks by the use of old clothes and other articles that had belonged to men dead of enteric fever.

The experiments of Alessi, referred to in the report for 1894, page 26, have been repeated by Abbott, who found, in contradiction to Alessi, that the gases of putrefaction do not predispose to enteric fever. But, nevertheless, it must be believed that the inhalation of the gases of putrefaction by men accustomed to fresh air, cannot but have a depressing effect, and render the men an easier prey to the microbe of any infectious disease. Hueppe, page 239.

Piorkowski found that the enteric bacillus, like some others, can penetrate into the interior of unbroken eggs.

The possibility of enteric fever being an auto-infection has several times been raised by medical officers in India, and it is a favourite view with the Lyons school of bacteriologists. Thus Rodet asserts:—

"The coli and the enteric are varieties of the same, and there are other varieties within and beyond. The coli is the cause of typhoid, because the enteric bacillus is extremely seldom found in water, but almost always the coli; and in the dejections the colon bacilli are numerous, while the enteric bacilli are rare. As the bacillus coli is present in every body, the change to the enteric bacillus must be rare, and the new characters are acquired within the body."

McWeeney also says:—

"I do not believe that there is a radical division between the typhoid bacillus and the bacillus coli. The characters which distinguish them are all mutable. There are clinical facts which show that auto-intoxication from one's own bowels may take place, and the bacillus coli may set up inflammation in the Peyer's patches and toxic substances may be absorbed, giving rise to symptoms the same as in typhoid fever."

Again, Hueppe remarks:—

"There are two views at present. The one which up to now seems to me to have the best foundation is that the enteric bacillus and the bacillus coli are two different species. The other is that an ordinary intestinal saprophyte, the bacillus coli, is a resident parasite, which under special influences becomes invasive, and appears as the enteric bacillus."

Other observers have drawn attention to the extended pathogenic activity of the *bacillus coli*.

The researches of Lösener, referred to on page 26 of the report for 1894, in the course of which he found bacilli indistinguishable from that of enteric fever in the intestinal contents of a buried pig, in specimens of earth, in the fæces of a healthy

man, and in the waste water of his laboratory, have been extended by Remlinger and Schneider of the Val de Grace hospital laboratory, who at the meeting of the Paris Society of Biology of 18th July 1896 reported that with the help of Elsner's medium they had isolated micro-organisms from water, earth, and the stools of men not sick of enteric fever, which were not to be distinguished from the enteric bacillus, gave the specific reaction with Pfeiffer's serum, and stood the potato, gelatine, indol, and lactose tests. They found this bacillus in eight out of 36 specimens of water, in six out of 10 specimens of earth, and in the stools of three men suffering respectively from leucocythæmia, malaria, and nephritis. Two of the specimens of water came from a town in which enteric fever was prevailing, five from places in which typhoid fever had been present months before, though during the epidemic the same methods had not demonstrated the presence of the bacilli. The specimens of earth were obtained partly from the surface of the ground and partly from a depth of 50 centimetres. Twelve out of 18 specimens of these bacilli killed guinea-pigs, when injected into the peritoneum, but it was found that a previous inoculation of Pfeiffer's serum prevented a fatal result. Other organisms were found in water, earth, and fæces, which had the morphological and biological characters of the enteric bacillus, but did not react to the serum. If these results be confirmed, they seem likely to necessitate some change in present views as to the causation and mode of origination of enteric fever.

It has been well said that not only does India now receive, under the short service system, a large and constant supply of susceptible material, but that each case may contribute a large number of bacilli to aid in the spread of the disease. The aims of the sanitary officer must therefore be to destroy as many bacilli as possible, to prevent the survivors obtaining entrance to the bodies of the soldiers, and to maintain the bodily resisting power of the latter, not only for the sake of the individual, but because it has been suggested that pathogenic microbes passing through a body whose resistance they have been unable to overcome, may be rendered weaker. Hueppe, page 239. As to the first point, the recommendation made in the report for 1894, that the stools and urine* of enteric fever patients should be totally destroyed by fire, may be here repeated, with the addition that this process should be continued for at least 10 days or a fortnight after convalescence has been established. All water and milk should be boiled before use, and should not be liable to contamination between boiling and use. Water should also be treated with permanganate of potassium according to the directions issued by Mr. Hankin. The next desideratum should be striven after by the exercise of cleanliness in all things. Constant attention should be devoted to the water supply from its source to the mouths of men. It should run from the source in closed pipes, and there should be no possibility of contamination between the standpipe and the consumer. The milk supply requires equally great care, including the establishment of proper dairies under efficient supervision; and both these points are receiving much attention. The manufacture of aërated drinks should everywhere be put under strict regulation and supervision; and, where it is possible, such drinks should be stored after manufacture for 14 days before being used. The men should be fully warned as to the danger of partaking of food and drink from unknown, or from obviously unclean sources. For so long as the bazars and the habits of the people who live in them remain as dirty as at present, and so long as the soldier goes thither to eat and drink all sorts of filth, so long will this second desideratum be imperfectly attained. The third object would no doubt to some extent be gained by the substitution in the garrison of India of older and more seasoned men; but this may perhaps be regarded as beyond the range of practical proposals. The next best thing is greater attention to the personal hygiene of the men.

Finally, it must be borne in mind that, though now-a-days more is known about enteric fever than in former times, still much remains involved in mystery; and that, as all the avenues of approach of the disease may not have been discovered, no single point of hygiene should be neglected. In the barracks the men are cleanly and enjoy, or ought to enjoy, pure air, earth, water, and food; but in the bazars close by is filth abounding, always at hand to poison the men, when they make their too frequent visits, and ever ready for the numerous accidents which mysteriously introduce its sullying and fatal presence into these laboriously and gradually attained cantonment purities.

Most medical officers lay stress on the influence of climate acting on young and unseasoned soldiers; but the medical officers at Fatehgarh, Pachmarhi, Benares, and

* The bacillus is said to have been found in the sputum and also in the sweat.

Bangalore, give instances where men of greater age or longer service did not enjoy any comparative exemption. Three men are said to have disembarked in India with the disease on them; and some new arrivals were supposed to have contracted the disease *en route* from Bombay to Agra, to Sialkot, and to Bangalore. Again, medical officers frequently noted, especially in the case of hill stations, that the disease must have been contracted before arrival, either from impurities encountered on the march, or from a cause existing in the previous station; so that the station where the disease was treated was not always the station in which it was contracted. In a number of the cases admitted at Kuldunnah, Gharial, and Peshawar, the disease had been contracted on service with the Chitral Field Force. It was supposed that the Field Force took enteric fever with it from India, and that local circumstances, such as deficient conservancy establishment, fouling of the ground, and the presence of large numbers of flies, favoured the increase and spread of the disease. Some patients acknowledged having used foul water in the jungle, on the rifle range, or when marching from the plains to the hills. The water supply was considered to be liable to contamination at Chakrata, Nowshera, Mhow, and Bangalore. The combined result of 10 stations was that 72 cases occurred in total abstainers, and 129 in non-abstainers, or 36 and 64 per cent. respectively. But, as their average annual strengths cannot be obtained, no conclusion can be drawn as to the relative liability of these two classes. The medical officer at Lucknow bewails the fact that though the new water supply by pipes was in use throughout the year there was more enteric fever than in any of the preceding three years, and believes that the men frequently contract enteric fever, as they do venereal disease, in the native bazars. Like many other medical officers, he looks with the greatest suspicion on the liquid refreshments of which the men partake in those places. The danger of a double water supply, one for drinking and one for washing purposes, is noted in the reports from Chaubattia, Satara, Nasirabad, and Taragarh. Other dangerous practices mentioned are washing dishes in dirty water, and bathing in foul ponds. At Deesa impure sand in the filters was suspected, and at Ahmednagar dirty water was found in the filters. In several cases, the specific microbe was reported to have been discovered in the water or other article. The medical officer at Kirkee complains that there was just as much enteric fever, though the milk supply is now so carefully supervised. The milk was suspected at four stations, and at one of them, Dagshai, the enteric bacillus is said to have been detected in it. As usual, the comparative immunity of women and children is given as a reason for not considering milk to be a frequent vehicle of the infection. For the period 1886–95 the enteric fever ratios per 1,000 of strength for India were as follows:—

	Admissions.	Deaths.
Men	19·6	5·28
Women	6·8	1·82
Children	3·5	0·69

The medical officer at Bangalore found by inquiry that only about 4 per cents of the men were drinkers of milk. The only reference to dust as an agent in the propagation of enteric fever is made in the Lucknow report, but only as a general surmise. The relative immunity of Calcutta, Murree, and Hyderabad (Sind) was ascribed to the excellent water supply, and, in the case of Murree, to careful sanitary supervision. Putting the bazar out of bounds was said to have been efficient in checking the disease at Nasirabad. A limited severe outbreak among officers at Bangalore was not traced to its source, but the sanitary condition and surroundings of their houses seem to have been bad. One of these officers suffered from his second attack of the disease. Out of the 1,870 cases of enteric fever which occurred throughout the army of India in 1895 about 30 are noticed as having declared themselves among patients in hospital or among attendants. Out of these 11 were in hospital for venereal diseases, 12 were in hospital for other diseases, and 7 were attendants on enteric fever cases.

There was an increase of both morbidity and mortality from enteric fever in 1895. As compared with the corresponding ratios of 1894, the admission and death ratios rose respectfully by 5·4 and 0·97 per 1,000 of strength. There were 1,870 admissions and 477 deaths, against 1,484, and 409 in 1894. The average number of men constantly sick from enteric fever was 220, and the average duration of a case was 52 days. The total loss of service due to the disease was about 80,216 days, men on field service being excluded from the calculation.

The following table shows a n increase in total fever mortality, which may be ascribed to the greater usefulness and less average length of service of the soldiers of to-day :—

	1870–79.			1881–90.†			1894.			1895.		
	Enteric Fever.	Other Fevers.*	Total of both.	Enteric Fever.	Other Fevers.*	Total of both.	Enteric Fever.	Other Fevers.*	Total of both.	Enteric Fever.	Other Fevers.*	Total of both.
Army of India	2·03	1·42	3·45	3·79	·70	4·49	5·75	·56	6·31	6·72	·59	7·31

* Intermittent, remittent, and simple continued fevers.
† Excluding troops on active service in Burma during 1885 to 1887.

It shows in the years 1894 and 1895, as compared with the decennia, an increase of mortality from enteric fever, accompanied by a decrease in mortality from the other fevers, which is probably partly due to increased susceptibility to enteric fever on the part of the army, from youth and recent arrival, and partly to the increasing frequency with which the diagnosis of enteric fever has been made.

The following table shows enteric fever in the geographical groups in the decennium 1882–91, and in the last two years :—

Admissions per 1,000.

Period.	Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalayan.	Indus Valley and North - Western Rajputana.	South-Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Convalescent Depôts.
	I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XIIa.	XIIb.
1882–91	4·1	4·7	5·4	24·3	18·6	12·5	17·4	12·0	4.5	10·9	18·4	10·7
1894	2·6	5·3	7·6	23·8	27·2	21·1	32·6	19·8	4·1	13·4	25·1	19·2
1895	18·9	4·9	11·0	37·8	24·9	27·0	24·4	21·7	9·6	10·3	26·6	16·6

It shows that Groups V, VI, VIII, and XII*a*, especially, are apt to have high ratios of admission from enteric fever, and Groups I, II, and X low ratios. It also shows at a glance how the groups compare with each other in 1895, and how 1995 compares with 1894, or with the decennium. Group V had the highest ratio of 1895, and in it also the percentage of enteric fever in total admissions was greatest.

The distribution of enteric fever throughout the year by stations and months may be studied in Table VIII. But the following shows those garrisons which had an average strength of over 1,000 in 1895, with the decennial ratios for reference :—

Stations.	1895.		Decennium 1882–91.	
	Admission-rate.	Death-rate.	Admission-rate.	Death-rate.
Lucknow	56·2	15·36	32·7	5·62
Chakrata	52·0	15·69	15·1	4·85
Peshawar	49·2	16·80	10·4	4·33
Meerut	44·5	12 30	15·9	4·93
Umballa	40·9	80·9	10·6	2·49
Bareilly	35·7	4·12	34·2	8·67
Agra	31·1	14·75	13·9	4·46
Secunderabad	28·2	5·43	19·4	5·40
Poona	22·7	6·27	10·5	3·58
Rawalpindi	21·2	7·93	19·9	5·34
Wellington	19·4	5·28	5·7	1·95
Mhow	17·8	3·89	19·2	5·31
Quetta	11·9	2·55	14·0	3·67
Ranikhet	11·8	2·94	32·6	5·01
Rangoon	10·0	4·56	2.6	1·80
Ferozepore	9·3	4·63	11·8	3·85
Colaba	9·2	3·35	4·6	1·59
Bangalore	8·4	·93	18·1	3·66
Fort William	6·8	3·86	3·7	2·21
Kurrachee	4·9	1·64	22·4	4·06
Aden	4·8	3·85	2·0	1·25
Fort Dufferin	3·9	·97	8·1*	*3·10
Sialkot	0·8	·78	32·1	8·13

* (Four years).

The high position occupied by the decennial admission ratios of Bareilly, Lucknow, Ranikhet, and Sialkot will be observed, and the low position of the ratios of Aden, Calcutta, Bombay, and Rangoon. The enteric fever of stations may be studied with the aid of Tables III, IV, and VIII.

With regard to the relation of the mortality from enteric fever to age and length of residence in India, the results confirm those of former years. The ratio of mortality from enteric fever per 1,000 of strength was greatest in the age-period, 20-24 (8·22), and the relative liability of the same period was 47 per cent., that is the highest; the total number of deaths from enteric fever in that age-period was 293, and out of 100 deaths from all causes in that period 55 were from enteric fever; out of the total number that died at all ages from enteric fever 77 per cent. were between 20 and 24 years of age. Again, the ratio of mortality from enteric fever per 1,000 of strength was highest in the first year of residence in India (10·83), and the relative liability for the same period was 32 per cent., that is the highest; the total number of deaths from enteric fever in the first year was 141, and out of 100 deaths in the first year of residence, 59 were from enteric fever. Out of the total number that died at all periods of residence from enteric fever, 37 per cent. were in the first year of Indian residence.

The age-period 20–24 included 53 per cent. of the total strength of the army, and in the same period the liability to fall sick of enteric fever was greatest. In the succeeding three periods the liability gradually declined; but there was a slight rise again after 40, due, however, to only one admission. The greatest liability to get enteric fever was in the first year of Indian residence, and thereafter the liability rapidly declined. Since arrivals have increased, and since the percentage in the army of men under 25 years of age, and of men with less than five years' Indian residence has been gradually mounting, the admission ratio from enteric fever has also been rising. The greater has become the supply of susceptible material, the more the disease has prevailed.

Respiratory diseases. Notwithstanding the increase of influenza, respiratory diseases caused less sickness than in the preceding year. The admission rate fell from 34 per 1,000 in 1894 to 33 per 1,000 in 1895, and the death-rate from 0·98 to 0·57. The admission rate from pneumonia was 4·4 per 1,000, against 3·7; but the death-rate fell from 0·75 to 0·51.

Dysentery and diarrhœa. The admission and death-rates from dysentery were greatly, and those from diarrhœa somewhat increased, the former from 27 per 1,000 in 1894 to 35 per 1,000 in 1895, and the latter from 21 to 24 per 1,000. The death-rate from dysentery rose from 0·60 in 1894 to 1·04, and diarrhœa from 0·06 to 0·07. The increase was for the most part due to service in the Chitral campaign.

Hepatitis. Both the admission rate and the death-rate from hepatitis rose, the latter from 1·24 in 1894, to 1·45, of which 1·41 was due to abscess of liver.

Venereal disease. The admission rate from venereal disease was 522·3 against 511·4 in 1894. There were 3,164·84 against 3,062·18 men constantly sick in hospital from venereal disease, equivalent to over three regiments. The average stay of a case of veneral disease in hospital was 31·49 days against 30·77; and the total loss of service was about 1,155,167 days against 1,117,696; men in field service being excluded from the calculation. There were 15 deaths and 353 invalidings directly due to venereal disease. The highest ratios were at Nowgong, Cawnpore, and Indore; and the greatest increase of ratio at Cawnpore, Solon, Calicut, Mallapuram, and Poonamallee. The total venereal ratios of the commands may be compared in the table at page 44. In 34 stations the admission rate from secondary syphilis was over 100 per 1,000 of strength; and in 28 others it was over 75 per 1,000.

Statistics show clearly that the arrival year by year of fresh batches of young unmarried men under the short service system has been accompanied by an increase of venereal disease. Since 1878 the number of fresh troops arriving in the country has, as a rule, been much greater than before. The gradual rise in the percentage of men under 25 years of age in the army and of men under five years' Indian service has been pretty uniform, as has been the well-marked decline in the number of married men; and the same may be said of the gradual rise in the venereal ratio. As youth and recent arrival have become more common in the army, venereal disease and enteric fever have not unnaturally increased in frequency of occurrence.

An interesting pamphlet by Commenge gives comparative venereal statistics of the English, French and Russian armies, with some account of venereal disease in the Italian army. The following statistics, except the ratio of the Indian army, are from Bondesen:—

Venereal Admissions.

	1889–93. Ratio per 1,000.		1889–93. Ratio per 1,000.
Indian Army	453	French Army	44
English Army	212	Belgian Army	32
Italian Army	104	German Army	27 } about.
Austro-Hungarian Army	65	Danish Army	27 } about.

How far these ratios are trustworthy is not known in this office. An article has recently appeared, pointing out that in different countries the arrangements for the admission of cases is so different that a statistican, in instituting comparisons between the armies of two countries is, unless he is aware of these differences, and allows for them, sure to blunder. Perhaps it should also be borne in mind that the English army is not a conscript army. However, the above table is probably right in making the English ratios much higher than the others.

The following table shows the admission rate for venereal disease as far back as the records for India as a whole permit. The heading "primary syphilis" includes the local sore throughout:—

Venereal Disease in the Army of India.

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.
1872	61·2	22·4	179·0	1884	90·2	22·4	293·9
1873	53·4	20·4	166·7	1885	122·1	28·7	342·7*
1874	68·3	25·2	192·7	1886	157·9	33·3	389·5*
1875	67·1	25·1	205·1	1887	142·1	29·4	361·2*
1876	59·8	23·9	189·9	1888	142·1	32·4	370·6
1877	65·2	22·1	208·5	1889	225·1	51.2	481·5
1878	95·3	22·0	271·3	1890	220·7	66·3	503·5
1879	79·2	24·5	234·8	1891	159·2	60·0	400·7
1880	87·9	23·1	249·7	1892	161·1	57·8	409·9
1881	92·0	23·1	260·5	1893	213·6	61·6	466·0
1882	87·6	23·2	265·2	1894	248·1	74·6	511·4
1883	87·2	23·5	270·3	1895	239·0	84·9	522·3

* Including Troops on active service in Burma.

The figures in the above table show a more or less continuous rise in the incidence of venereal disease, more specially since 1885; and the increase in the ratio of secondary syphilis is of grave importance, more particularly with regard to the individual. No man who has not been effectually cured of syphilis can be reckoned upon as an efficient soldier; and the mischief is not confined to the individual, as the physical weaknesses are continued to succeeding generations.

33. The statistics for 1895 of the chief diseases having been examined, it will be interesting now to compare the mortality of the past five years from some of the principal causes with that of earlier periods:— Past and present mortality.

Died per 1,000 *of Strength.*

	India.		
	1891–95.	1881–90.	1870–79.
Enteric Fever	5·81	3·81	2·03
Cholera	1·38	1·46	3·22
Hepatitis	1·18	1·33	2·19
Dysentery	·65	·80	1·48
Phthisis pulmonalis	·58	·74	1·18
Respiratory diseases	·75	.59	·97
Remittent fever	·53	·52	1·28
Diarrhœa	·06	·09	·12
Total from all Causes	15·37	14·24	19·34

The increase in enteric fever and the decrease in hepatitis are probably due to the influence of the short service system, as is explained in page 42. The diminution of mortality from cholera, dysentery, and diarrhœa may perhaps be put down to improved hygiene. The rise in the total death rate is probably due to the number of military expeditions, and to three out of the five years having been bad cholera years in India. If the period had been 10 years the rise would in all likelihood have been obliterated, and perhaps changed into a fall.

Invaliding. In the whole army of India 1,763 men were invalided, or 24·82 per 1,000 of strength, against 1,808 and 25·43 in the preceding year. The ratio for the decennium 1881–90 was 27·35. In page 42 it is shown that invaliding has been reduced since the introduction of the short service system. The proportion of invalids to strength was lowest in the Punjab Command, highest in the Madras Command.

Thirty-three per cent. of the total number invalided were discharged as unfit for further service. The following table shows that this percentage was lower than it had been for some years:—

	Proportion Discharged.				
	1891.	1892.	1893.	1894.	1895.
India	34	40	39	39	33

The following table shows the diseases which accounted for invaliding of not less than 1 per 1,000 of strength:—

Intending Ratios per 1,000 *of Strength.*

Syphilis and Gonorrhœa	4·97
Malarial fevers	3·10
Debility	2·39
Circulatory diseases	1·93
Tubercle of the lungs	1·20

The ratio of invaliding from mental diseases decreased by a half. There were 24 cases of melancholia, 16 of dementia, and 12 of mania.

Invaliding according to age and Indian Service.—The percentage of men who were invalided while under 25 years of age to the whole number invalided was 66 against 60. The percentage of men under 25 in the strength of the army was 55 against 54.

Of the total number of men invalided 36 per cent. were of less than two years' service, and 86 per cent. were of less than five years' service. With this is to be considered the fact that 83 per cent. of all the men in the strength of the army were of less than five years' service.

With regard to individual diseases. The highest invaliding ratio per 1,000 of strength from venereal disease was in the age-period 20·24, and the relative liability for that period was 32 per cent.; the total number invalided for venereal disease in the same age-period was 222, and of 100 invalidings in the age-period 21 were due to venereal disease; of the total number invalided for venereal diseases at all ages 63 per cent. were in that age-period. Again, the highest ratio of invaliding for venereal disease was in the fourth year of Indian service, and the relative liability in that year was 20 per cent.; the total number invalided for venereal disease in the fourth year was 75, and of 100 invalided in the fourth year 26 were due to venereal disease; of the total number invalided for venereal diseases at all periods of residence 21 per cent. were in the fourth year.

Statistics of Officers. The vital statistics of officers show that the death-rate for *all* officers in the British Army was 11·10, and that for the Indian Army 9·62. Enteric fever caused more deaths among the British than among the Indian officers, apparently because Indian officers have to serve first with British regiments, and it is known that youthful and newly arrived men are more liable to take the disease than others.

Sickness among women decreased, but the mortality was higher. The constantly sick-rate, though reduced, was still somewhat high:— Statistics of women.

Period.	Average annual strength.	Admission-rate per 1,000.	Constantly sick-rate per 1,000.	Death-rate per 1,000.
1881–90	3,352	837·5	30·6	18·86
1894	3,157	926·8	41·1	14·57
1895	3,194	804·3	35·2	17·85

The chief causes of admission were debility, ague, and the diseases peculiar to women. Among the diseases which caused increased admissions were small-pox, enteric fever, pneumonia and dysentery; while from influenza, cholera, and ague admission was lessened. Debility caused 34 per cent. of the total sickness, and ague 19 per cent.

The chief causes of death were puerperal affections, enteric fever, remittent fever, tubercle of the lungs, and pneumonia. Among the diseases which gave much increased mortality were small-pox, enteric fever, pneumonia, dysentery, and puerperal affections. Mortality from cholera and diarrhœa was diminished. Puerperal affections caused 18 per cent. of the total deaths, and enteric fever 14 per cent.

That both sickness and mortality among children were lowered in 1895 is seen in the following table:— Statistics of children.

Period.	Average annual Strength.	Admission-rate per 1,000.	Constantly sick-rate per 1,000.	Death-rate per 1,000.
1881–90	6,286	633·5	23·4	50·22
1894	5,680	732·2	32·6	44·89
1895	5,699	598·5	26·2	41·24

The chief causes of admission were ague, respiratory diseases, and diarrhœa. Among the diseases with raised admission-rates were enteric fever, cholera, and smallpox; while admission from influenza, measles, respiratory diseases, and eye diseases was lessened. Ague caused 20 per cent. of the total sickness, and respiratory diseases 15 per cent.

The chief causes of death were debility (including immaturity at birth), diarrhœa, convulsions, and teething. Among the diseases from which there was increased mortality were cholera, small-pox, diphtheria, ague and remittent fever. Mortality from enteric fever, respiratory diseases, and convulsions was diminished. Debility caused 15 per cent. of the total deaths, diarrhœa 14 per cent., convulsions 12 per cent., and teething 11 per cent.

Native Troops.

There was less sickness among the Native troops in 1895 than in the preceding year; malaria, influenza, and cholera being less prevalent. The rise in the general death-rate, and in particular the rise in the death-rate from pneumonia, were due to exposure and hardship incidental to the Waziristan and Chitral expeditions. Sickness and mortality in 1895.

Year.	Average Strength.	Ratio per 1,000.							
		Admissions into Hospital.	Constantly Sick.	Deaths from					Mortality, including absent Deaths.
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All Causes.	
1882–91	118,111	1,020	34	1·45	1·47	2·90	·77	13·09	16·61
1894	127,844	897	31	·56	1·44	2·87	·51	10·76	13·59
1895	129,655	794	30	·41	1·20	4·20	·53	11·60	15·71

The chief causes of admission were ague, bowel complaints, and respiratory diseases. Among the diseases with raised admission rates were pneumonia, tubercle of the

lungs, dysentery, diarrhœa, and scurvy. Among those with lessened rates were influenza, cholera, ague, simple continued fever, respiratory diseases other than pneumonia, and venereal diseases. Ague caused 36 per cent. of the total admissions.

The chief causes of death were pneumonia and remittent fever. Among the diseases which caused increased mortality were small-pox, tubercle of the lungs, and pneumonia. Among those from which mortality was lessened were cholera, remittent fever, circulatory diseases, and respiratory diseases other than pneumonia. Pneumonia caused 36 per cent. of the total deaths, and remittent fever 10 per cent.

The total number invalided for discharge was 1,875, and the chief causes of invaliding were debility, ague, respiratory diseases, and venereal diseases.

If the following table be compared with that at page 44, it will be seen how much less the Native soldier suffered from enteric fever, simple continued fever, ague, tubercle of the lungs, diarrhœa, hepatitis, venereal diseases; and much more from remittent fever, small-pox, pneumonia, other respiratory diseases, and dysentery than his European comrade. These relations are unusual with regard to ague, but usual in the case of enteric fever, remittent fever, respiratory diseases, dysentery, hepatitis, and venereal diseases.

Ratios of Commands.

* For complete detail of diseases, *see* Table XXIX.

Of the commands the Punjab was the most unhealthy, having the highest constantly sick and death rates. That this command suffered the most from remittent fever, pneumonia, and other respiratory diseases, dysentery, and diarrhœa was due to the

Waziristan and Chitral expeditions. The Bombay Command, which had the highest admission-rate, was the worst of the commands as regards admissions from influenza, ague, and scurvy.

The following table shows the statistics of all the native troops serving in Burma and the Andamans. Of these troops in 1895 about 99 per cent. belonged to the Madras Army:—

Years.	Average Annual Strength present.	Ratio per 1,000.						
		Admissions into Hospital.	Constantly Sick.	Deaths from				
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All Causes.
1890	10,353	1,510	69	5·02	5·31	1·84	4·15	38·83
1891	11,401	1,676	76	1·75	2·98	1·84	4·03	36·31
1892	11,333	1,349	57	2·29	2·29	2·29	3·09	29·12
1893	10,326	1,092	48	·87	1·45	2·42	1·36	19·85
1894	10,500	809	35	1·43	·95	1·14	1·43	13·90
1895	9,952	827	37	·80	·50	·80	·80	10·55

The table shows that the death-rate has been reduced year by year. Sickness was not high, though higher than in the previous year.

The table which follows shows that both for the decennium and in 1895 Groups II, III, IV, VII, and XII, had high constantly sick ratios; and that both for the decennium and in 1895 mortality from respiratory diseases was greatest in the Indus Valley and in the Hills. Geographical groups.

1895 Constantly sick rate	24·4	42.9	39·1	37·0	23·1	29·9	35·3	24·4	26·8	29·8	26·1	37·1	29·9
1895 Death-rates from— Cholera	—	1·20	—	—	1·69	—	—	·69	·77	—	·99	—	·41
1895 Death-rates from— Respiratory diseases	1·87	·75	2·66	·99	1·23	4·60	12·48	3·21	2·17	·65	1·32	5·97	4·87

Burma Coast had the lowest admission ratios from ague and tubercle of the lungs; Burma Island the highest from cholera and ague, and the lowest from pneumonia; Assam the highest from remittent fever, tubercle of the lungs, and diarrhœa; Bengal-Orissa the highest from dysentery, and the lowest from simple continued fever; the Indus Valley the highest from pneumonia and other respiratory diseases; Central India the lowest from dysentery; Southern India the highest from simple continued fever, and the lowest from remittent fever, respiratory diseases other than pneumonia and diarrhœa; and the Hill stations the highest from influenza and scurvy. Assam and the Hills, where the Gurkhas, who are foreigners, are stationed, had the highest venereal ratios.

Of the large stations throughout India with a strength of not less than 1,000 the following returned the highest death-rates:—Dehra Dun, 20·78; Kohat, 22·67; Edwardesabad, 36·06; Dera Ismail Khan, 19·13; Dera Ghazi Khan, 23·15; Dharmsala, 20·97.

In Dehra Dun and Dharmsala, which are garrisoned by Gurkhas, tubercle of the lungs was the chief cause of death; and in the other four, which are frontier stations, pneumonia was the chief cause.

Principal diseases: Influenza.

Attention having been directed to the health statistics of India, of the commands, of the geographical groups, of stations, and of regiments, it will be convenient now to consider some of the chief diseases. Influenza decreased, there having been 910 cases, 7·0 per 1,000 of strength, against 1,155 cases, 9·0 per 1,000 of strength, in the preceding year. The number of stations affected was 22 against 37, 10 of those attacked in 1895 having also suffered in 1894. The geographical groups affected in both years were IV, V, VI, VII, VIII, IX, XI, XII, and Extra India. Groups I, II, and III were not affected either in 1894 or in 1895. In proportion to strength the Hills was the group most severely affected; whilst the greatest numbers of cases occurred in the Hills and in the Indus Valley.

The following table shows the monthly progress of the disease since the beginning of 1890. The maximum month varied from year to year; but over the period as a whole most cases occurred in April and March, and fewest cases in October and September:—

Influenza.

Years.	Number of Admissions into Hospital in each Month.												Total.
	Jan.	Feb.	March.	April.	May.	June	July.	August.	Sept.	Oct.	Nov.	Dec.	
1890	1	8	2,460	5,118	492	82	55	—	—	—	1	—	8,217
1891	—	—	1	—	105	259	123	106	51	22	17	215	899
1892	681	371	511	149	40	5	5	7	—	1	7	18	1,795
1893	8	28	65	99	95	13	9	7	—	3	53	404	784
1894	159	203	232	384	143	11	5	—	1	1	5	11	1,155
1895	26	28	53	76	110	25	60	57	19	17	31	408	910
Total	875	638	3,322	5,826	985	395	257	177	71	44	114	1,056	13,760

The greatest numbers of cases occurred at Chaman, Abbottabad, and Dera Ghazi Khan. At the first named station the disease lasted throughout the year, but in the other two it was confined to December. The following table shows that in 1895 the Native troops were somewhat less severely affected than the European troops, much less severely than the prisoners:—

Years.	Per 1,000 of Average Strength.											
	Influenza.						Pneumonia.					
	European Troops.		Native Troops.		Prisoners.		European Troops.		Native Troops.		Prisoners.	
	Admission.	Death.	Admission.	Death.	Admission.	Death.	Admission.	Death.	Admission.	Death.	Admission.	Death.
1890	33·4	·03	64·3	·41	78·6	·67	4·6	·90	16·7	3·96	18·5	5·71
1891	5·5	·04	7·0	·09	19·0	·29	2·6	·54	11·6	2·53	17·0	4·87
1892	12·7	·01	14·1	·15	56·7	1·26	3·5	·62	13·6	3·26	18·4	5·56
1893	·3	—	6·2	·20	6·4	·09	3·4	·70	12·3	2·75	15·9	3·95
1894	3·4	·01	9·0	·16	41·0	·43	3·7	·75	12·9	2·87	15·4	4·31
1895	7·8	·03	7·0	·08	20·3	·15	4·4	·51	17·5	4·20	16·4	4·00

It also shows how the death-rate from pneumonia has fluctunted year by year with the admission-rate from influenza. It has already been explained that the unusually high death-rate from pneumonia in 1895 was the result of service in Waziristan and Chitral.

Cholera.

There were 75 cases of cholera with 53 deaths against 116 with 71 in the preceding year. The admission-rate per 1,000 was 0·6 against 0·9, and the death ratio 0·41 against 0·56. Cases occurred in every month except March, the maximum months being July, September, and November. In Burma Inland the cases bore the highest

proportion to strength. The greatest numbers of cases occurred in the Deccan and in Burma Inland. Among stations Malegaon, Fort Dufferin, and Fyzabad had most cases, but 11 was the highest number of cases at any one station. The circumstances attending the chief outbreaks will be discussed, so far as they are of etiological importance, in the section History of Chief Diseases.

To ague was due 36 per cent. of the sickness of the Native army. The admission-rate from ague fell considerably in 1895. In 1895 Burma Inland was the most malarious group, and Burma Coast the least malarious. The most malarious month was October, the least malarious March. Remittent fever caused 10 per cent. of the total deaths, and it was at its maximum in August. Judging from the frequent discrepancy between diagnosis and *post mortem* record in the case of prisoners, it is not improbable that among native troops also the fevers returned as remittent are not all malarial but include some cases of fever due to organic disease. Fevers.

The ratio of admission from enteric fever in the Native army in 1895 was 0·2 per 1,000, and the death-rate 0·07, against 0·3 and 0·05 in the previous year. The corresponding decennial ratios of 1882–91 are 0·3 and 0·09. The following table shows that the ratios for European troops are very unlike those for Native troops and prisoners :—

	1882–1891.		1895.	
	Admissions.	Deaths.	Admissions.	Deaths.
European troops	14·7	4·13	26·3	6·72
Native troops	·3	·09	·2	·07
Prisoners	·2	·10	·4	·13

Post mortems are rarely obtainable in the case of Native soldiers; but among prisoners nearly every fatal case of disease is subjected to *post mortem* examination. Under these circumstances the fact that the ratios of prisoners and sepoys for a 10-year period are practically identical appears to show that the Native troops really suffer less than the European; though it does not show that there may not be more cases of enteric fever among both Native troops and prisoners than are at present diagnosed during life or after death. Again, the following table shows that the fever mortality in the European army is not the same in amount, which indicates that the difference is not altogether a mere matter of diagnosis :—

Causes of Death.	Died per 1,000 of Average Strength.		Relative Liability in Percentages.			Percentage in Deaths from all Causes.	
	European Troops.	Native Troops.	European Troops.	Native Troops.	Total=100.	European Troops.	Native Troops.
Ague	·25	·59	30	70	100	1·7	5·1
Remittent fever	·30	1·20	20	80	100	1·9	10·4
Simple continued fever	·04	·02	67	33	100	·3	·2
Enteric fever	6·72	·07	99	·1	100	44·0	·6
Total	7·31	1·88	80	20	100	47·9	16·3

The total fever mortality among the Native troops in 1894 was to the total fever mortality among European troops as 1 : 3·9. For the period 1886–91 the corresponding ratio was 1 : 1·9, and for 1894 it was 1 : 3·0. Again, among European troops 48 per cent. of all deaths in 1895 were from fevers; only 16 per cent. among Native troops. It appears, then, that Native soldiers and prisoners are less liable to enteric fever than Europeans are.

The question of the immunity, or apparent immunity, of natives of India as regards enteric fever has been frequently discussed in former reports. At page 33 of the Report for 1890 was noticed the suggestion that it was the fact of coming from comparatively pure England that made the modern English soldier so liable to contract enteric fever in India, while the natives of India having lived for generations in specific

filth, had acquired a certain tolerance or immunity; the difference of the behaviour of measles in England and in Fiji being adduced as an illustrative parallel example. The same view is prominently brought forward in the *Indian Medical Gazette* for August 1896, page 294, in a review of Mr. Archdale Reid's "The Present Evolution of Man." This interesting article concludes as follows:—

> The fact that many medical men believe that enteric fever is really prevalent among native *children*, though often called by other names, is an argument for rather than against this view; for, just as in biology, a trait which appears late in the ontogeny corresponds to a trait which appeared late in the phylogeny, so the power of resisting the germs of enteric fever must have appeared late in the Indian races, that is, after generations of exposure to it and consequent survival of the fittest. Therefore, this power will appear late in the individual, so that children are still liable to be attacked.

In the whole Native army of India 22 cases with 9 deaths were returned as enteric fever, against 33 cases with 6 deaths in 1894. In only two cases were *post mortems* obtained; and the lesions described support the diagnosis.

Respiratory diseases.

The ratio of admission remaining the same, the death ratio from respiratory diseases rose:—

Period.	Ratio per 1,000 of Strength.			
	Respiratory Diseases.		Pneumonia.	
	Admissions.	Deaths.	Admissions.	Deaths.
1886–95	50	3·75	13	3·02
1894	53	3·63	13	2·87
1895	53	4·87	18	4·20

Respiratory diseases are the chief cause of death in the Native army, and in 1895 no less than 42 per cent. of all deaths were due to them. For respiratory diseases other than pneumonia the highest admission ratios were those of Indus Valley, Central India, Burma Coast, and the Hills, and the lowest that of Southern India. The highest death-rate was that of Assam, while there were no deaths from those diseases in Burma Inland and Western Coast.

Pneumonia.

The table given in the preceding paragraph shows that the admission and death-rates rose much. This, as has already been explained, was due to the exposure endured by the regiments on active service in Waziristan and Chitral. The admission and death ratios were highest in the Indus Valley and the Hills, and the percentage of pneumonia to total deaths was there also highest. Both in the Indus Valley and in the Hills pneumonia was most prevalent in the cold months; and the same was the case for India as a whole.

Pneumonia has been shown separately in the tables of this Report only from 1889; that is why the period 1889–95 has been adopted in the following:—

Pneumonia, 1889–95.

——	Jan.	Feb.	March.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Total.	Ratio per 1,000.	
														Admitted.	Died.
European troops	255	180	183	186	117	69	66	55	53	89	170	296	1,719	3·5	·64
Native troops	2,358	1,667	1,310	911	465	337	345	252	308	667	1,384	2,871	12,375	13·8	3·18
Prisoners	1,717	1,368	1,181	914	728	584	609	532	639	857	1,138	1,676	11,943	16·9	4·75

The Europeans suffered much less than the Natives, probably because they are more accustomed to cold, because they are better clothed, and because they are more nutritiously fed. The high ratios among prisoners indicate the necessity for increased attention to ventilation, to clothing, and to the prevention of scurvy and malaria. Throughout the period the ratios of prisoners have been higher than those of Native troops, except in the year 1895, in which the Native troops were campaigning in Waziristan and Chitral. The table also shows that the coldest months had most

pneumonia, January and December being the maximum months for all three bodies of men. Group VI, VII, VIII, and XII, which in the following table show the highest ratios, also have the maximum in January and December; and these are groups which have a marked cold weather, a great range of temperature between day and night in the cold weather, and, generally, high ratios of admission from malaria or scurvy, or both. Again, of the 11 stations of European troops that had the highest ratios from pneumonia during the period, three belonged to Group VI, three to Group VII, and five to Group XII; of the 15 stations of Native troops with the highest ratios, two belonged to Group VI, nine to Group VII, two to Group VIII, and two to Group XII; of the 23 jails with the highest ratios, two belonged to Group IV, two to Group V, 10 to Group VI, seven to Group VII, one to Group VIII, and one to Group IX; or, taking all the worst stations and jails together, 31 per cent. belonged to Group VI, 39 per cent. to Group VII, and 14 per cent. to Group XII. Rawal Pindi, with its maximum in January and December, and Quetta with its maximum in March and November, had the highest pneumonia admission ratios for European troops; Edwardesbad with its maximum in January and December, the highest for Native troops; and Shikarpur with its maximum in January, February, November, December, the highest for prisoners:—

Pneumonia, 1891–95.

European troops	1·7	·26	2·0	·23	1·6	·13	2·5	·49	4·8	1·01	4·0	1·45	3·5	·62
Native troops	10·6	1.70	8·2	1·43	4·6	·55	8·0	1·44	18·7	4·26	—	—	13·6	3·12
Prisoners	23·7	5·64	13·3	3·96	7·8	2·56	6·3	2·10	15·6	4·92	—	—	16·6	4·54

Among medical officers of Native regiments on the frontier the opinion is prevalent that the pneumonia occurring there is often of a very infectious type; but it is at the same time acknowledged that malaria-saturated or scurvy-tainted men exposed to chill are peculiarly vulnerable. Similar conditions among the prisoners in the jails of the Punjab often tend to the same result.

From what has been brought forward in this paragraph it seems probable that in all the three bodies of men pneumonia is to a considerable extent a preventable disease; and that it might, with some success, be combated by free ventilation, without draughts, so as to diminish the risk of infection; by suitable clothing at all times, but especially by the use of extra warm clothing, such as a jersey, from sundown in the cold weather; by a sufficiency of food with good vegetables and antiscorbutics; and by the prophylactic issue of antiperiodics. Of course, there are difficulties in the way of carrying out these measures thoroughly, especially in the case of the Native troops; but probably more could be done than has hitherto been attempted. In any case it is proper to point out what ought to be striven after.

Dysentery.

From dysentry, the admission and death-rates were somewhat higher than in the preceding year. The highest admission-rates were in the Punjab Command, and in the Bengal-Orissa group. The death-rate of Native troops from dysentery was to that of the Europeans as 1 : 1·96 ; and the percentage of dysentery in total cases of death was 4·6 in the case of Native troops, and 6·8 in the case of European troops. The admission rate of Native troops, however, was much higher than that of European troops, 48·6 to 35·5.

Venereal diseases.

The following table is given to compare with the corresponding one in the section on European troops, page 55 :—

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.
1877	11·5	5·3	26·7	1887	12·6	6·1	27·4
1878	16·3	5·8	37·5	1888	13·5	5·4	31·5
1879	16·5	7·0	37·1	1889	16·6	6·4	38·9
1880	15·0	5·8	33·3	1890	16·0	6·9	41·1
1881	17·9	7·2	39·5	1891	13·6	6·9	37·9
1882	14·7	5·9	34·4	1892	14·1	7·9	39·6
1883	13·0	6·5	31·6	1893	13·3	9·0	36·4
1884	11·0	5·3	27·9	1894	13·8	8·2	32·3
1885	11·2	5·9	30·1	1895	13·1	7·3	41·3
1886	13·7	6·0	28·1				

The figures for India are not available for the years before 1877. All the venereal ratios of Native troops run at a much lower level than those of European troops; and there is not the same tendency to increase in the ratios of the former as in those of the latter, there having been no change in the Native army corresponding to the introduction of the short service system in the European army.

A comparison of the tables will show that the lowest ratios for both European and Native troops were those of the Punjab Command; the highest for European troops the Bengal Command, and the highest for Native troops the Madras Command. In all the commands the ratios of Native troops were much lower than those of European troops. Among the European troops of India there were 522 admissions for every 1,000 men, among the Native troops only 31.

The admission-rate for India was exactly 1 per 1,000 less than in 1894. There were six deaths and 86 invalidings attributed directly to venereal disease.

Those Native troops that are serving in regions farthest away from their homes appear to be the most affected by venereal disease. The Gurkhas are the most conspicuous example of this.

Finally, the following table of death ratios is given to show how the past five-year period compares with the decennium immediately preceding it :—

Died per 1,000 *of Strength.*

Diseases.	Army of India.	
	1891–95.	1881–90.
Cholera	1·19	1·28
Enteric fever	·08	·08
Ague	·84	·66
Remittent and simple continued fevers	1·40	1·45
Phthisis pulmonalis	·68	·67
Respiratory diseases	3·85	3·84
Dysentery	·67	·81
Diarrhœa	·34	·65
Scurvy	·04	·13
Anæmia and Debility	·48	·65
All causes	12·61	13·44

The total death-rate has been reduced; and in the case of the diseases shown the reductions are greater in amount than the increases, as well as greater in number.

Jails.

Sickness and mortality in 1895.

The year 1895 was one of much sickness, though the death-rate was considerably reduced. The weather of the whole year was less disturbed than usual, and the most noteworthy feature of the monsoon rains was the general deficiency over the whole of India north of lat. 18. Among the free population influenza, cholera, and malaria appear to have been less prevalent than in the preceding year.

Year.	Average Annual Strength.	Ratio per 1,000.									
		Admissions into Hospital.	Constantly Sick.	Deaths from							
				Cholera.	Remittent fever.	Dysentery.	Diarrhœa.	Respiratory diseases.	‡Phthisis Pulmonalis.	Anæmia and Debility.	All Causes.
1882–91* - -	89,642	1,093	38	2·91	1·60	6·84	3·93	5·99†	2·37	2·16	33·61

1895* - -	106,337	1,082	44	·80	1·20	7·15	2·31	5·14	2·54	1·49	27·61

* Excluding subsidiary jails. † From 1886. ‡ Tubercle, Pneumonic Phthisis and Hæmoptysis.

The chief causes of admission to hospital were ague, dysentery, abscess, and diarrhœa. Among the diseases with raised admission-rates were simple continued fever, tubercle of the lungs, pneumonia, dysentery, debility, and abscess. Ague caused 35 per cent. of the total sickness, and bowel complaints 16 per cent.

The chief causes of death were dysentery, pneumonia, tubercle of the lungs, diarrhœa, and debility. Among the diseases with mortality lessened in 1895 were cholera, respiratory diseases, debility, and diarrhœa. Dysentery caused 26 per cent. of the total deaths, and pneumonia 14 per cent.

The following statement shows for each administration, except the Andamans, the proportion of prisoners in 10,000 of the population. Some of the prisoners of each province have been transported to the Andamans, and these are necessarily excluded from the calculation; so that the ratios are all somewhat too low:—

Ratio of prisoners per 10,000 *of population in each of nine administrations for* 1894 *and* 1895 (*Andamans excluded*).

Administrations.	Period.	General Population, according to Census of 1891.	Prisoners.		
			Average Number.*	Proportion per 10,000 of Population.	Deaths per 1,000 of Average Strength.*

* Excluding subsidiary jails. † From 1886. ‡ Tubercle, Pneumonic Phthisis and Hæmoptysis.

The prisoners of the Andamans, Assam, the North-Western Provinces and Oudh, Bombay, the Central Provinces, and Madras were more unhealthy than in the previous year; those of the last only slightly so.

In 1895 the three most unhealthy administrations were, in order, Assam, the Andamans, and the North-Western Provinces and Oudh; and the three most healthy were, in order, Madras, Berar, and Burma.

As compared with the decennial ratios, cholera mortality was reduced in all the administrations; dysentery mortality in Burma, Bengal, and the Punjab; dysentery and diarrhœa mortalities were increased in the Andamans, Assam, and Bombay; diarrhœa mortality was much* diminished, and dysentery mortality slightly increased in Madras. Mortality from respiratory diseases was increased in Bombay, Berar, the Central Provinces, and Madras; phthisis mortality rose in Burma, Assam, the North-Western Provinces and Oudh, the Punjab, Bombay, the Central Provinces, and Madras; and the total mortality increased in the Andamans, Assam, the North-Western Provinces and Oudh, Bombay, Berar, and the Central Provinces.

The great differences between the death-rates of the different administrations, as shown in the above table, are most striking. A uniform death-rate among jails distributed over such a wide geographical area, and placed under such different permanent climatic conditions, and frequently under such different temporary weather conditions (drought in one, excessive rainfall in another), could hardly be expected; but a smaller degree of variation might have been hoped for, as the result of accumulated knowledge and experience in the management of jails. Scarcity and the

* This is principally due to the cases of diarrhœa in 1895 having been returned as Catarrhal Inflammation of the Intestines.

prevalence of endemic and epidemic disease among the free population, undoubtedly affect the sickness and mortality in jails, but with the inmates of jails and their surroundings completely under control, it might have been expected that the practical benefits accruing from efficient sanitation and trained supervision would, in some of the instances, have been exemplified in a more striking manner.

The use of prophylactic doses of quinine or cinchonidine combined with iron and sulphuric acid before and during the malarious season of the year should be more extensively tried. In this matter the Punjab has taken the lead, and has already obtained some satisfactory results.

The Andamans had the highest mortality from remittent fever, and the lowest from pneumonia; Assam the highest from ague, diarrhœa and debility; the Punjab the highest from pneumonia, and the lowest from dysentery; Bombay the highest from tubercle of the lungs; the Central Provinces the highest from cholera, small-pox, enteric fever, dysentery, and respiratory diseases other than pneumonia; and Madras the lowest from diarrhœa and from debility.

In each 100 of the total deaths the proportion of fevers was greatest in the Andamans and Assam; of cholera in Burma and Bengal; of pneumonia, in the Punjab; of dysentery, in the Central Provinces; of diarrhœa, in Assam; of tubercle of the lungs, in Burma.

The Principal Officer of the Andamans, says:—"The water supply is not very "satisfactory. In the dry weather before the rains nearly all the wells run dry, and "the tanks become very low. There was a decided scarcity in several places before "the rains this year. Several improvements have been carried out during the year. "Wells have been deepened and tanks cleaned out and protected from contamination. "Several of the large stations are supplied with a patent boiler, and all stations are "supplied with *degchis* for boiling the drinking water. In many places the supervision "of the water is difficult, and the convicts, when at work in the forest, will drink any "water they can get. . . . . The great increase in admissions is due to the "severe prevalence of malarial fevers before and during the early months of the rains. "The daily sick-rate has not been so low for many years, a distinct proof that the "great increase in admissions was due to slight complaints. . . . . Aberdeen "and Phœnix Bay are the only stations which have proved unhealthy during the year. "A large number of convicts have been concentrated in these two places in connection "with the cellular jail and workshops, and malarial fevers and dysentery prevailed "severely among them. A patent boiler has been established in each place, and for "several months now the health has been satisfactory."

The season was of a favourable nature in Burma, the rainfall not excessive, and well distributed over the monsoon months. The drinking water in Upper Burma is not of such good quality as that in the Lower Province, but arrangments are gradually being introduced to sterilise all drinking water by boiling. All the jails in the administration, except five, were overcrowded at one time or other during the year, and in the case of the majority the overcrowding was chronic. Only four out of the past 33 years, namely, 1875, 1880, 1893, and 1895, had death-ratios under 25 per 1,000, and the death-rate of 1895, namely, 17·93, was the lowest of all.

Allowance having been made for the facts that the Native troops in Assam are also unhealthy, and that the tea-garden coolies, free or imprisoned, are, like the troops, imported foreigners, it may be said that the excessive mortality was mainly owing to the absence of proper care in the selection of prisoners employed on extramural labour in the tea-gardens, and to insufficient attention having been paid to the food, water, and clothing of those prisoners while they were so employed. The rules now issued with regard to the working of the system of extramural labour in the four jails where mortality was highest should be productive of the best results. The prisoners on admission into jail are in a low and anæmic state of health, perhaps to a greater extent than in any other province. This calls for a modification of the ordinary prison diet, a diet which may be suitable for men in ordinary conditions of health, but which is not calculated to bring up anæmic and under-fed individuals to the normal standard. The bedding supplied seems also not to afford sufficient protection against the winter cold, and measures are being taken to remedy this.

The year was reported to have been a healthy one in the province of Bengal generally, but the diminished mortality must, in great part, be ascribed to careful supervision, and to the intelligent and effective manner in which local conditions affecting the health of the prisoners have been met and overcome. A beginning was made in the prophylactic issue on a large scale of quinine or cinchonidine. Great

attention was given to the preparation and cooking of the food, and improved cooking ranges were introduced, where necessary. Good nutritious vegetables and anti-scorbutics were freely given, and the supply of milk from jail dairies was encouraged. These, and the measures taken in connection with the supply of drinking water, must be credited with the good general results obtained, and with the absence of all symptoms of scurvy in the central prisons, and their general absence in the others.

Bengal jails which obtain their water from municipal mains do not boil their water, but all the others do, and most of them have been supplied with Larymore's patent boiler for the purpose. Installations of the Pasteur-Chamberlain filter for the Naya Dumka and Motihari jails were ordered at the beginning of 1895, but delay has taken place in their supply from England. The disinfection of wells by permanganate of potassium has been started as a general practice; and for each jail has been purchased the simple apparatus required for the numerical estimate of microbes present in water.

The unhealthiness of the jails at Balasore, Chaibassa, Motihari, Naya Dumka, and Burdwan has been the subject of investigation by special medical committees, and it is hoped that the recommendations, which have met with the approval of Government, made for improving the local conditions, will be successful in reducing the sickness and mortality in those jails.

The Inspector-General of Prisons in the North-Western Provinces and Oudh states that the year 1895 was an exceeding unhealthy one, owing to a succession of bad harvests, and that "the people were consequently emaciated and reduced to a state "of starvation, and suffered a great deal from malaria." A great many of the admissions into the jails were necessarily in a weak state of health, and it is not surprising, he says, "that the sickness and mortality were high." In the year 1895 the mortality among the free population was 29·13 per 1,000, while the average of the previous years was 30·98.

The free population generally, therefore, appears to have been in an average state of health. In some of the districts, however, the medical officers report that a large number of the admissions into jail were in an extremely bad state of health. The greatest mortality occurred among the short-term prisoners, and the mortality among under-trial prisoners was high. Again, the mortality ratio of central jails was only about half that of district jails. All this tends to prove that the opinion expressed by the Inspector-General of Prisons as to the cause of the sickness and mortality is correct, notwithstanding the comparatively low provincial death-rate. The mortality in district jails would no doubt have been higher if efforts had not been made to control it. Medical officers appear to have exercised the powers entrusted to them by modifying the ordinary jail diets as was necessary, and by the issue of extra articles of diet to weakly prisoners.

An outbreak of fever, returned as relapsing, which will be noticed further on, occurred in the Moradabad jail.

The mortality of the Punjab in 1895 was lower than in any of the preceding 19 years, except 1894. If the 20 years period ending with 1895 be divided into four equal periods, it will be found that the mortality has steadily fallen from quinquennium to quinquennium. "These figures," says the Inspector-General of Prisons, "illustrate "how much has been done during the past 15 or 20 years to ameliorate the "condition of the prison population in this province. But the mortality of the jail "population is still higher than it ought to be, owing, no doubt, in some measure, "to the sanitary defects that exist in our jails, which it will take time and con-"siderable outlay of funds to remedy." The increase in the death-rate was due to an epidemic of influenza, which appeared in many of the jails during the month of December. Of the total deaths 38 per cent. were from pneumonia, a disease which has almost invariably been the chief cause of the mortality in the jails of the Punjab; and it seems desirable that extra warm clothing should be issued during the cold season to the prisoners in those jails where this disease is most prevalent, and that hospital accommodation with proper appliances for keeping the air at an equable temperature should be provided for patients admitted with respiratory diseases. The death-rate from dysentery and diarrhœa was the lowest in the record of the last 20 years, and these diseases caused no deaths in 21 out of the 33 jails of the province. The admissions under intermittent fever show a remarkable decrease, which is ascribed by the Inspector-General to "the comparative healthiness of the autumnal "months, and probably in some measure to the administration during the unhealthy "season of fever-prophylactics, large quantities of which were supplied to all jails."

Comparative experiments were made in the Mooltan Central Prison and in the district jails of Delhi and Lahore with regard to the effect on the health of the prisoners of boiled and of unboiled drinking water, but the results were not of a very decisive character. In the jails at Umballa, Ludhiana, Amritsar, and Karnal, where the water has been boiled systematically for some years past, the ratio of admissions into hospital for all diseases was 1,326, 1,295, 2,067, and 1,289, while for all other district jails as a whole the ratio was 1,314. For intermittent fever the ratios were 400, 177, 1,128, 645, and in all other district jails 582; and for bowel complaints the ratios were 276, 91, 268, 149, and in all other district jails 161.

Eight out of the 16 jails in Bombay were overcrowded throughout the year. Looking at the nature of the chief diseases, it is highly probable that the chief cause of the sickness leading to the mortality was in connection with the food issued to the prisoners. The scale of diet in use may theoretically meet the physiological requirements of these prisoners, but they are on a less liberal scale than those in certain other provinces, and to derive from them their full nutritive value it is necessary that the ingredients should be of the best quality, and that the cooking arrangements should be thoroughly efficient and carefully supervised. The Sind jails, as usual, had many cases of pneumonia, so that further improvements seem called for in the matter of clothing, and probably of ventilation. This gang, no doubt composed of selected men, "was "employed on the hardest form of labour in the way of digging and embankment "work"; they were lightly housed, and were exposed to all the variations of temperature and weather; yet they were particularly healthy, owing, no doubt, to the extra liberal diet which they received, and to the sufficiency of bedding and clothing supplied to them.

The high mortality at Akola, in Berar, has not been satisfactorily explained, but was not due to overcrowding, and was probably due to defects of quality or quantity in the food-grains, the vegetables, the antiscorbutics, and in the cooking. The indifferent water-supply in the last quarter of the year doubtless increased the sickness.

The Inspector-General of Prisons in the Central Provinces thus accounts for the increased mortality:—"The unfavourable conditions of the year previous continued "during the past year in an aggravated form. The rainfall was in some places "deficient and in others unseasonable, the seasons were unhealthy, and prices of food-"grains ranged higher than in 1894. The new admissions into jail were generally in "poor health and low condition, many of them being admitted at once into the infirm "gang or into hospital;" and he finds from the reports of the medical officers that "there is a general consensus of opinion that the excessive sickness and mortality of "the past year were induced, not by the circumstances and conditions existing in jails, "but by the consequences resulting from the privations to which the new admissions "had been exposed outside." The scale of diet in force appears to be adequate, provided the cooking be good; but from the experience of previous years, as well as of 1895, there is evidently something wrong with the supply of vegetables and anti-scorbutics. The difficulty of cultivating, under existing circumstances, nutritious varieties of vegetables at all seasons in quantities sufficient to meet the full requirements of prisoners liable to a scorbutic taint is undoubtedly a great one, but it is apparently being overcome in other parts of India.

In the districts of Madras generally the year was not so healthy as 1894; but, although sickness among the prisoners was higher than in 1894, yet the death-rate was, if cholera be excluded, the lowest on record. The Inspector-General of Prisons ascribes the low mortality to the great care given to the proper feeding of the prisoners, and he declares that a high rate of sickness and mortality shows that due care has not been taken in the "proper selection, preparation, and distribution of the food to the "prisoners." "That this is in practice," he continues, "the most important factor in "determining the health of the prisoners in jails in this country I am convinced, and "it is evident that the care devoted to the food can never be relaxed." Again:— "On the whole, the year 1895 was a decidedly wet one, and this fact probably "accounts for a good deal of the increased sickness." The daily issue of prophylactics in the feverish season of the year is to be introduced. As cases of phthisis pulmonalis are on the increase in the central prisons at Coimbatore and Vellore, steps have been taken for the segregation of the patients so affected. The jails at Parvatipuram and Cuddapah have been temporarily closed on account of their unhealthiness.

Progress in reduction of Death-rate.—The following shows a diminution of mortality in the jails of India under all the heads shown, except respiratory diseases, phthisis pulmonalis, and ague :—

Died per 1,000 *of Strength.*

Deaths from	1891–95.	1881–90.
Dysentery	6·56	7·28
Respiratory diseases	5·78	3·72
Diarrhœa	2·26	4·45
Cholera	2·34	2·90
Anæmia and debility	1·89	2·22
Phthisis pulmonalis	2·57	2·41
Ague	·70	·42
Spleen diseases	·20	·23
Hepatitis	·20	·22
Scurvy	·08	·12
Total from all Causes	30·63	34·98

The increase in respiratory diseases and in phthisis is, at least to a great extent, due to the epidemic of influenza, which began in 1890.

Mortality of Prisoners and of Troops compared.—A table is, as usual, here given to compare the mortality of prisoners in 1895 with that of soldiers. Taking the death-rate of European troops as unit, the death-rate of Native troops will be represented by 0·8, and the death-rate of prisoners by 1·8. The mortality of prisoners was comparatively high as regards cholera, bowel complaints, spleen diseases, debility, respiratory diseases, and tubercle of the lungs. Only from fevers was the European soldiers' mortality highest. The enormously greater liability of the prisoners to death from bowel complaints is well shown in the table. Among the prisoners over 34 per cent. of all the deaths were from bowel complaints, and 19 per cent. from respiratory diseases; among the Native troops 7 per cent. from bowel complaints, and 42 per cent. from respiratory diseases; and among the European troops 7 per cent. from bowel complaints, and 4 per cent. from respiratory diseases. While the liability of the Native soldiers to die from respiratory diseases was less than that of the prisoners, yet these diseases made up a larger percentage of the total deaths among the Native soldiers than among the prisoners. Again, fevers accounted for 48 per cent. of all the deaths among the European soldiers, 16 per cent. of all the deaths among the Native soldiers, and 9 per cent. of all the deaths among the prisoners. Taking the mortality of the Native troops from fevers as 1, that of the prisoners is 1·2, and that of the European troops 3·9. Taking the mortality of the Native troops from bowel complaints as 1, that of the European troops is 1·5, and that of the prisoners 12·4. Taking the mortality of the European troops from respiratory diseases as 1, that of the Native troops is 8·5, and that of the prisoners 9·1. The chief cause of death among European troops was fevers, among Native troops respiratory diseases, and among prisoners bowel complaints. Of course, for obvious reasons, too much must not be made of the comparison just instituted :—

Mortality of Prisoners compared with that of Soldiers in 1895.

Causes of Death.	Died per 1,000 of Average Strength.			Relative Liability in Percentages.				Percentages in Deaths from all Causes.		
	European Troops.	Native Troops.	Prisoners.	European Troops.	Native Troops.	Prisoners.	Total 100.	European Troops.	Native Troops.	Prisoners.
Cholera	·45	·41	·80	27	25	48	100	3·0	3·5	2·9
Fevers*	7·31	1·89	2·34	63	16	20	100	47·9	16·3	8·6
Bowel complaints	1·11	·76	9·46	10	7	83	100	7·3	6·6	34·3

All Causes	15·26	11·60	27·61	28	21	51	100	100·0	100·0	100·0

* Enteric, intermittent, remittent, and simple continued fevers. † Includes acute and chronic pneumonic phthisis.

General Population.

General remarks.

As has been pointed out in former reports, the statistics with which this chapter deals are in many cases very far from being accurate, but they are useful for purposes of comparison. In rural areas, where the collecting agency is generally illiterate, and underpaid, defects are to be expected, but in municipalities, where the registration of births and deaths is legally compulsory, better results might be hoped for. Registration in the municipal towns is, however, generally much less accurate than in the rural areas. The municipal authorities themselves are apparently not alive to the importance of correct statistics, and unless the Local Governments and administrations will bring pressure to bear upon the committees, it is to be feared that no improvement will be effected. Until vital statistics are completely and accurately registered, it must be impossible to measure accurately the effect of any efforts made to improve hygienic conditions.

The proposals for placing the executive of the Sanitary Department in a more satisfactory position, to which allusion was made in this report for last year, are still being considered by the Government of India in communication with Local Governments. The great difficulty is the lack of funds, but it seems that it will be very difficult to secure a uniform system for the whole country. It can be readily understood that, although an agency may be very suitable for Lower Bengal, an exactly similar agency would be useless and perhaps harmful in, say, the Punjab.

As in 1894, the highest birth-rate was recorded in the Punjab, and the lowest in Coorg. In Madras, Bombay, Bengal, Berar, and Lower Burma, the ratios were higher than in the previous year. In all provinces, it will be seen that the extreme birth-rates, both in urban and rural circles, vary very widely. In seven provinces the birth-rate was in excess of the death-rate, the excess ranging from 3·20 per 1,000 of the population in Bengal, to 14·6 in the Punjab. In the remaining five provinces the numbers of deaths were greater than the numbers of the births in millesimal ratios varying between 12·7 in Berar, and 2·92 in Coorg.

Throughout the country, except in the small provinces of Assam, Berar, and Coorg, the death-rates were lower in 1895 than in the previous year. The highest death-rate was recorded in Berar and the lowest in Coorg. As in the case of births, the differences between the highest and lowest death-rates recorded were very great in both urban and rural circles in every province.

In the following table, the deaths recorded from all causes in the different provinces are shown month by month :—

Statement showing the Deaths from all Causes according to Months in the different Provinces of India during the year 1895.

Province.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Ratios of Deaths per 1,000 of Population.

The population of Bengal, excluding the Chittagong Hill Tracts and the new district of Angul, in which vital statistics are not yet registered, was found to be 71,070,233 at the last census in February 1891. This figure is used for the calculation of ratios. In the towns registration is compulsory. In the rural areas, since 1892, the statistics

have been collected by the village watchmen and recorded by them at the police stations and out-posts, which are the registering centres. Although improvement in registration has been brought about, much remains to be done, and means are being considered to render the existing arrangements more efficient. The provincial Sanitary Commissioner points out, however, that, until the people themselves begin to take some interest in registration and lend their aid voluntarily to the registrars, and until the compulsory clauses of the Registration Act are more rigorously enforced in the towns, there is not much hope of obtaining accurate results. In 1895, there were 2,049 persons convicted of neglecting to register, against 1,923 in the previous year, and from them a sum of Rs. 3,153-14 was realised as fines, or Rs. 495-15 more than in 1894; 427 persons were merely warned.

The total number of births registered was 2,548,623, or 34·59 per 1,000 of the population, as compared with 32·81 in 1894 and 35·66 in 1893. Among the districts, the highest rates were recorded in Noakhali (46·61), Backergunge (45·92), and Hazaribagh (42·71); and the lowest in Hooghly (27·24), the Twenty-four Parganas (25·73), and Calcutta (16·05). The average birth-rate in the towns was 23·92 per 1,000, against 22·77 and 26·27 in 1894 and 1893 respectively. In no town is the calculated provincial average birth-rate of 51·8 per 1,000 approached; the highest rates obtained were 44·17 in Jamalpore, 42·75 in Chatra, 42·27 in Jamui, and 41·60 in Roserah. In 13 towns, the rates were between 40 and 35; in 29, between 25 and 30; in 34, between 30 and 25; in 31, between 25 and 20; and in 36, below 20. With one or two possible exceptions, defective registration is common to all the towns, so that the birth-rates are greatly understated. The ratios are also lowered by the custom of many women who live in towns, returning to their family homes in the rural areas to be confined. In some towns there is a preponderating male population; this is the case in Jhalakati in Backergunge, from which, as usual, the lowest birth-rate was returned, 5·49 per 1,000. In the rural areas the average birth-rate was 35·13 per 1,000, against 33·32 in 1894, and 36·14 in 1893. In 42 rural areas, rates above 45 per 1,000 were obtained, including three over 60, namely, Phulbaria (65·00), and Kalihati (62·98) in Mymensingh, and Kushtia (62·51) in Nadia. In the province, generally, there were 106 males born for every 100 females.

The total number of deaths registered was 2,231,458, and the death-rate was 31·39 per 1,000, as compared with 34·88 and 28·21 in 1894 and 1893 respectively. Among districts, the highest rates were recorded in Jessore (41·48), Calcutta (39·66), Nadia (38·80), and Hooghly (38·67); the lowest in Noakhali (25·27), Lohardaga (24·82), the Sonthal Parganas (23·22), and Singhbhum (19·62). In the towns, the average recorded mortality decreased from 35·34 in 1894, to 34·40 per 1,000 in 1895, ranging from 59·44 in Bhadreswar in Hooghly, to 15·41 in Chapra, and 12·68 in Jhalakati. In the rural areas the average death-rate fell from 34·85 in 1894 to 31·24 in 1895, the figures ranging from 41·52 in Jessore to 19·46 in Singhbhum. In the province, generally, the average death-rate among males was 33·76 per 1,000, as compared with 29·04 among females; the corresponding figures for 1894 were 37·16 and 32·61. The death-rates, per 1,000 living of infants under one year of age, were, for males 216·59, and for females 175·53, as compared with 234·38 and 191·23, in 1894. At all age periods the male death-rates were the higher, the difference being least between the ages of 15 and 20. Among the various classes the highest death-rate was registered for Muhammadans, 32·96 per 1,000; the death-rate among Hindus was 31·05; among Christians it was 18·31, among Buddhists 22·74, and among "other classes" 23·69.

The number of European seamen who arrived in the Port of Calcutta in 1895 was 18,015, against 17,900 in the previous year, but the average number present daily in the Port was less, 1,413 as compared with 1,481. The number of deaths was 40 against 27, and the death-rate per 1,000 19·56 against 18·23 in 1894. The average native population afloat is estimated to have been 25,630, and the number of deaths among them was 123, or 4·79 per 1,000 against 5·34 in the previous year.

The population of that portion of the province of Assam, where the registration of vital statistics was fully carried out in 1895, was, according to the census of 1891, 5,021,084, and the population of the area, where registration was compulsory, was 105,431. As in the previous year, statistics were collected in certain villages of the Garo Hills and in Kohima, which are not included in the general figures. In the selected Garo villages, the average birth-rate was 36·75 per 1,000 of the population, against 25·82 in 1894, and the death-rate 29·79 against 30·01. In Kohima, where the population consists of 1,247 males and 534 females, the birth-rate was 20·21 per 1,000, about 9 per 1,000 less than in 1894, and the millesimal death-rate 19·09, against 16·84 in the preceding year.

The number of births registered in the different districts of the province was 155,631, and the birth-rate was 31 per 1,003, against 31·10 in the previous year. In Cachar and Sylhet the birth-rates were 31·09 and 34·05 respectively, giving an average birth-rate in the Surma Valley of 33·62 per 1,000, which is much higher than the average of the Brahmaputra Valley, 28·40, or than the rate obtained in the selected areas of the Khasi and Jaintia Hills, 25·79. In the districts of the Surma Valley and in Goalpara, where the highest birth-rate, 42·29 per 1,000, was recorded, the collecting agency is paid; in the other districts the *gaonburas* who furnish the statistics being unpaid cannot be punished for remissness. The lowest rate of all, 22·07 per 1,000, was returned from the Nowgong district; there has been much sickness in this district for some years, but the very low birth-rate is mainly due to defective registration. About 30 per cent. of births in the province, as a whole, escape record. The average birth-rate in the nine head-quarter towns, where registration is legally compulsory, fell from 24·28 per 1,000 in 1894 to 20·80 in 1895, ranging from 29·26 in Dibrugarh to 16·96 in Sylhet. While it is a fact that there is a great excess of males in these towns, the birth-rates are very much understated. In 1891 the number of females in the head-quarter towns was 25,171, the number of births in 1895 was 1,413; calculating the ratio on double the number of females, 50,342, the birth-rate is only 28·07 per 1,000; now the calculated birth-rate for Assam is 48, so that in the head-quarter towns little more than half the actual numbers of births are registered. The average birth-rate in the 11 sub-divisional towns rose from 29·97 in 1894 to 31·24 in 1895; extreme rates of 53·86 and 8·58 per 1,000 were recorded in North Lakhimpur and Mangaldai, respectively; in the other sub-divisional towns the rates varied between 37·60 in Barpeta and 21·68 in Maulvi Bazar. In these towns the male population is to the female in about the proportion of 3 to 2. Estimating the birth-rate on double the female population, it is about 38 per 1,000.

The number of male births registered was 108 to every 100 female births; in the Surma Valley the percentage was 106, while in the Brahmaputra Valley it was 109.

The number of deaths registered was 169,304, or 13,673 more than the births. The death-rate was 33·72 per 1,000, as compared with 30·69 in 1894. The death-rates in Cachar and Sylhet were 32·01 and 32·41 per 1,000 respectively, giving an average for the Surma Valley of 32·37 in 1895, as compared with 27·62 in the previous year. In the Brahmaputra Valley, the average rate was 35·33, highest in the districts of Goalpara (42·72) and Nowgong (42·28). As registration in the latter is very defective, the actual mortality in that district was probably the highest in the province. The lowest death-rate in the Brahmaputra Valley was 28·82, recorded in Sibsagar, but this is much higher than the 22·76 per 1,000 registered in the Khasi and Jaintia Hills. In the head-quarter towns, the average death-rate increased from 25·55 per 1,000 in 1894, to 28·87 in 1895. If the deaths which occurred in the dispensaries are included, the average rate was 41·60, against 37·02 in 1894. Excluding these deaths, the highest rates were 52·61 and 48·70 per 1,000 recorded in Tezpur and Dibrugarh, respectively, and the lowest 17·91 and 12·95 in Sibsagar and Shillong. In the sub-divisional towns the average death-rate was 48·23 per 1,000, including deaths in the dispensaries, and 43·47 if these are excluded. Neglecting such deaths, the highest rates were 70·08 per 1,000 in Barpeta and 45·78 in Mangaldai, and the lowest, 23·96 in Maulvi Bazar, and 18·46 in Hailakandi. On an average, there were recorded the deaths of 113 males for every 100 females. In Nowgong 150 male deaths were registered for every 100 of females.

In the Surma Valley, and in the province as a whole, the highest mortality occurred in December and November, and the lowest in February. In the Brahmaputra Valley, the largest number of deaths was registered in May and the next largest number in June.

Calculated on the number of children under one year of age when the census was taken in 1891, the ratio of deaths per 1,000 of infants was 191·29 among males, and 176·60 among females. Between the ages of one year and five years, the millesimal death-rates were 39·01 among boys, and 37·79 among girls. Excepting persons between the ages of 15 and 30, the death-rates of males were higher than those of females. The death-rate among Hindus, 30·81 per 1,000, was followed by rates of 33·13, 35·43, and 55·14, among Muhammadans, Christians and "other classes" respectively.

The total number of births recorded in the North-Western Provinces and Qudh in 1895 was 1,637,235, as compared with 1,862,035 in the previous year. Although the year was exceptionally healthy, and the births exceeded the deaths by no less than

5·77 per 1,000, it will be noticed that the birth-rate, 34·90, was considerably lower than the rate recorded in 1894, which was 39·70, and lower than the quinquennial average, 37·47. The prevalence of severe sickness, particularly malarial fevers, in the previous year, probably accounts for the falling off in the birth-rate. Among the districts, the highest rates were recorded in Bulandshahr, 55·43 per 1,000, followed by Aligarh 52·36, Etah 51·29, and Agra 51·04. In the districts of Partabgarh, Benares, Naini Tal, Fyzabad, Jaunpur, Ballia, Ghazipur, and Azamgarh, the rates were below 26·0 per 1,000. In 24 of the 48 districts, the rates were higher than the average. In rural areas, the average birth-rate was 34·29 against 39·80 in the towns; in the former, the rate was nearly 4 per 1,000 below the quinquennial mean, in the latter, it was more than 7·0 per 1,000 above it. Among the towns there were great deviations from the average, the extremes, excluding hill stations and Brindaban, where the circumstances are peculiar, having been 64·27 in Fatehpur-Sikri, and 24·83 in Saharanpur. The percentage of male to female births in the province generally was 109·62, slightly higher than in 1894, when the percentage was 109·58, and this again was higher than the figure of the previous year, 109·47.

The number of deaths recorded was 1,366,443, or 627,335 less than in 1894. The death-rate was 29·13 per 1,000, against 42·51 in that year, and 33·34, the average of the previous five years. Among the districts, the highest rates were registered in Kheri (44·54), Naini Tal, which includes the Tarai (43·57), followed by Hamirpur (40·89), and Saharanpur (40·79); the lowest rates were registered in Partabgarh (21·97), Allahabad (21·78), Mainpuri (21·02), and Ballia (20·71). The average death-rate in rural areas was 28·58 per 1,000 against 33·46 in the towns, the rates among the latter, excluding hill stations, varying between 75·64 per 1,000 in Deoband, and 17·28 in Bareilly. With the exceptions of Fyzabad (51·22) and Benares (45·30), in none of the larger towns were high death-rates recorded, but among the smaller towns high rates were registered in Deoband (75·64), Baghpat (59·92), and Kashipur (48·17). In 23 municipalities the deaths were more numerous than the births. In some of these the prevalence of malaria and other circumstances partially explain this, but in the majority registration is at fault. As the provisions of the Vaccination Act are enforced in the municipalities, and the vaccinators are furnished with copies of the birth registers, it may be that parents not wishing to have their children vaccinated do not register their births. Among the various classes the Hindus had the highest death-rate, 29·22 per 1,000, then the Muhammadans, 28·68, and then "other classes," 24·79. Among infants under one year the ratios of mortality per 1,000 living were 217·87 for males and 208·32 for females; among boys and girls between one year of age and five, the ratios were 47·88 and 46·68 respectively. In the age-periods from 15 to 30 the death-rates of females were higher, at all other periods they were lower, than the death-rates of males. In January the number of deaths was greater than the average of that month, but the death-rate fell in February, and although showing the customary rise in April and May, remained below the mean throughout the year, reaching the maximum in December. The cause of the unusual rise in November and December is believed by the Provincial Sanitary Commissioner to be the abnormally high temperature in the former month.

The percentages of omissions detected in registers examined by civil, revenue, and police officers, were as regards births 2·78, and as regards deaths 2·64. There were 241,988 cases tested by the vaccination staff, the detected omitted percentages were of births 1·46, and of deaths ·72. In only 25 out of 103 municipalities were fines imposed for neglecting to register. The total number of persons fined was 1,068, and the amount realised Rs. 267-15-6.

In recent reports details have been given of the special efforts being made in the Punjab to improve the registration of vital statistics. The measures taken have, of course, been mainly towards the detection, by means of existing machinery, of omissions in the registers. Village registers are examined by the Sanitary Commissioner and by his deputy, by District Officers, Civil Surgeons, Tahsildars and Naib Tahsildars, and by the members of the Vaccination Staff. In 1894 five Divisional Inspectors of Vaccination and Registers were specially appointed. During 1895 considerable numbers of omissions were detected by the Sanitary Commissioner, by his deputy, and by the Civil Surgeons of Umballa and Gujranwala. The Tahsildars and Naib Tahsildars discovered 4,029 omissions, as compared with 1,555 in 1894; this is an improvement, but in many districts the inspections made by these officials seem, so far, to be of little use. The vaccinators inspected the registers in 15,839 villages, and detected the omissions of 13,042 births and of 3,652 deaths, as compared with 305 and

78, respectively, in 1894. The five special Divisional Inspectors discovered in the registers of 2,988 villages, the omissions of 10,835 births and 6,269 deaths. For every 100 villages inspected the Tahsildars discovered 30 omissions in the registers, the Vaccinators 105, and the special Inspectors 572. All these omissions were brought to the notice of the District Officers concerned, and were duly entered in the registers. The laws regarding the compulsory registration of births and deaths are available in 151 municipal towns, but they do not seem to be generally enforced. During 1895, 117 persons were fined for failing to report. The aggregate of the fines was Rs. 99, against Rs. 164 realized in the previous year.

In 1894 the birth-rate in the Punjab was 43·93, the highest ever recorded. In 1895 the rate was almost as high, a total of 901,584 births yielding a rate of 43·86 per 1,000 of the population according to the census of 1891. The highest district birth-rates were recorded in Gujranwala (54·4), Jhang (51·9), Gurgaon (51·7), Rohtak (50·9), and Ferozepur (50·7). Excluding the hill districts of Simla and Kangra and the frontier districts, the birth-rates in the remainder, with five exceptions, varied between 50 and 45 per 1,000. The exceptions were the districts of Amritsar (42·7), Gurdaspur (39·7), Jullundur (39·1), Umballa (38·7) and Hoshiarpur (37·2); the Provincial Sanitary Commissioner attributes these low rates to the unhealthiness of these districts in 1894. In the frontier districts since 1894 there has been a steady improvement in the registration of births, particularly in Kohat, Bannu, and Dera Ismail Khan; for instance, the average birth-rate in Kohat for the five years ending 1893 was 25·9 per 1,000, in 1894 it had increased to 40·4, and in 1895 to 42·0.

The average birth-rate in the rural circles was 44·3 per 1,000, as compared with 40·0 in the towns. Among the latter, the highest rates were recorded in Chiniot, Palwal, Chunian, Sialkot, Kaithal, Panipat, and Maghiana, all over 50 per 1,000; the lowest in Tanda, Urmar, Kartarpur, and Kohat, 30 per 1,000, and Sadhaura 27.

The percentage of male as compared with female infants born was 110·6, or 1·2 per cent. less than in 1894. In Peshawar the percentage was 141·4, compared with 153·9 in the previous year, and in Dera Ghazi Khan 128·9, compared with 127·1. With regard to Peshawar, the Deputy Commissioner is of opinion that the apparent preponderance of male births is mainly due to carelessness in the reporting of births generally.

The total number of deaths registered was 601,972, equivalent to a death-rate of 29·29 per 1,000 of the population, as compared with 37 in 1894, and 37·3, the mean of the previous five years. In only two districts, Simla and Umballa, were the numbers of deaths registered in excess of the births. The highest death-rates were recorded in Umballa (42·55), Karnal (37·17), and Delhi (36·96); the lowest in Shahpur (20·26). In rural circles the average death-rate was 28·8 per 1,000, as compared with 33·7 in the towns. Among the larger towns, the highest death-rate was recorded in Jagadhri, 50·12 per 1,000; after Jagadhri came Delhi, Soneput, Karnal, Umballa, Amritsar, Kaithal, Panipat, and Rawal Pindi, with rates between 43 and 39. The lowest rates were 26·39, 26·26, and 21·06, recorded, respectively, in Jalalpur, Gujrat, and Bhera.

The death-rate of the Hindu population was 30·41, as compared with 28·40 among Muhammadans, and 14·37 among Native Christians. The death-rates among infants under one year of age were for males 218·05, and for females 210·14 per 1,000 living. In certain districts, namely, Jullundur, Ludhiana, Ferozepore, and Amritsar, the deaths of female infants greatly out-numbered the deaths of males. Among children over one year of age and under five, the death-rates were, for boys 40·63, and for girls 43·14 per 1,000. Except in infancy, and during the age-periods over 40, the female death-rates were the higher. In the province generally 112·2 deaths of males were reported for every 100 deaths of females.

The highest mortality occurred in November and December, and the lowest in February and March. In the four hill sanitaria, Simla, Dharmsala, Dalhousie, and Murree, the average birth and death rates were respectively 23 and 32 per 1,000; and in the 30 cantonments the average birth-rate was 9 and the average death-rate 12 per 1,000.

In the Central Provinces vital statistics are collected by the village *Kotwars*, most of whom are illiterate villagers, badly paid for their work. From the *Kotwars'* books the entries are copied into the police registers, both sets of entries being compared by the native Superintendents of Vaccination. Errors in the police registers can result only from incorrect copying, but the Superintendent of Vaccination is supposed to make a house-to-house enquiry to discover births that may have been omitted by the

Kotwars. The native Superintendents inspected 2,801 villages, and detected a large number of discrepancies, but less, perhaps, than might have been expected, considering the collecting agency; indeed, the provincial Sanitary Commissioner thinks that the *Kotwars* do wonderfully well, allowing for the disadvantages under which they labour. In the municipal towns registration is compulsory, the compilation this year, for the first time, having been carried out by the Civil Surgeons. During the year 379 persons were fined an aggregate sum of Rs. 394-6-6 for omitting to report births and deaths, and 338 others were warned for the same offence.

In 1895 the number of births recorded was 317,432, or 51,452 less than in the previous year. The birth-rate, which was the lowest registered for 15 years, was 33·41 per 1,000 as compared with 38·82 in 1894, and 39·39, the quinquennial mean. In all of the districts, except four, Nimar, Burhanpur, Betul and Chhindwara, there was a decrease in the birth-rate as compared with 1894. The falling off in the birth-rate is attributed to the excessive sickness prevalent in 1894, to the scarcity and privation from which the people in many of the districts have suffered for some years past, which has limited the number of marriages, and has led to emigration of many unable to obtain employment and food at home. All these causes have contributed to lessen the actual number of births, but, in addition, the anxiety suffered by those in straits for food have made them careless in reporting births.

Among the districts, in only three, Nimar, Betul and Chhindwara, were rates over 40 per 1,000 registered, the lowest rates were 24·09 in Damoh, and 20·69 in Saugor. In 14 of the districts, against 11 in 1894, the birth-rates were lower than the death-rates. But, while in 1894 the excess of births over deaths in the province as a whole was 1·60 per 1,000 in 1895, the excess of deaths over births was 3·34 per1,000.

The average rural birth-rate was 33·63 per 1,000 against 30·33 in the 47 towns, in 35 of which the deaths exceeded the births in number. The highest birth-rates were 70·76 per 1,000 recorded in Multai, a town of 3,505 inhabitants in the Betul district, 50·85 in Mohgaon, and 46·86 in Wardha; in five other towns rates over 40 per 1,000 were registered. The lowest rates were 14·0 and 18·97, recorded respectively in Sambulpur and Hatta, and from 19 other towns, including Seoni (22·04), Jubbulpore (22·62), Saugor (23·37) and Raipur (26·18), rates under 30 per 1,000 were returned. The percentage of male to female births in the whole province was 105·61.

The total number of deaths recorded was 349,137, equal to a death-rate of 36·75 per 1,000. This is nearly 4 per 1,000 in excess of the quinquennial mean, and only ·47 per 1,000 less than the high death-rate of 1894. In that year the mortality was mainly due to a severe epidemic of influenza and to fevers; in 1895 influenza appeared in a mild form in three districts only, and the fatal cases of fever diminished by 17,133. On the other hand, in 1895 there were 8,463 more deaths due to cholera, and 5,144 more due to small-pox than in the previous year. The death-rates in the districts ranged from 57·06 in Nimar, 53·45 in Narsinghpur, and 51·86 in Saugor to 26·45 in Bilaspur, 25·70 in Raipur, and 22·73 in Sambalpur. The average death-rate in rural circles was 36·55 as compared with 40·07 in the towns. In 14 towns death-rates over 50 per 1,000 were registered, including the following very high rates, 78·38 per 1,000 in Badnur, 73·89 in Multai (both in Betul), 64·22 in Deori, and 61·88 in Rehli (both in Saugor). The lowest rates were 23·92 recorded in Mandla, 22·30 in Dhamteri, and 20·11 in Sambalpur. The heaviest mortality occurred in the months of August, September and October, the lowest in February.

Among infants under one year of age the death-rate per 1,000 living for males was 384·30, and for females 342·15; among boys and girls between one year and five years of age, the death-rates were, respectively, 51·63 and 43·67. At all age-periods the male death-rates were the higher. The millesimal death-rate among Muhammadans was 39·89, among Hindus it was 33·54, and among "other classes" 53·93.

In Berar, as described in the report for last year, the village officials collect and register vital statistics, and the police compile and classify them. The village records are tested by the Superintendents of Vaccination. Whilst inspecting the results of vaccination in a village they examine the registers. If the number of entries is suspiciously low a house-to-house visitation is made, until the names of a considerable number of infants are obtained, the names of infants who have died subsequent to vaccination being also noted. The list of names are then compared with the registers, and omissions are reported. Omissions of births are more frequent than omissions of deaths. During the year 1,793 village registers were thus examined against 2,293 in 1894, and 6 per cent. were found to be defective. Besides these inspections many officers, including Deputy Commissioners, Civil Surgeons, officers of the Police and *Tahsildars* examined, in all, 6,200 registers, of which 6 per cent. were found defective.

The total number of births recorded was 105,952, or 11,193 more than in 1894, and the birth-rate was 37·2 per 1,000, compared with 33·3 in the previous year, and 38·9, the mean of the previous five years. Except in Basim, where there was a decrease of ·1 per 1,000, in all the districts the birth-rates were higher than in 1894, the excess ranging between 6·4 per 1,000 in Buldana, where the birth-rate in 1895 was 44·2 and 1·1 in Wun, where the rate was 25·4. These were the two extreme district rates. The provincial Sanitary Commissioner does not believe that the low and decreasing rates recorded in Wun and Basim are altogether due to the backwardness of registration in these districts, but partly to a real falling off in the number of births from bad harvests and deficient food, which have led, in many instances, to reduction in the number of the villagers. The average birth-rate in the rural circles was 36·9 as compared with 40·1, the average in the towns. The urban rates were the higher in all districts, except in Ellichpur and Akola, where they are apparently reduced by the comparatively low rates registered in the towns of Ellichpur, Akola, Khamgaon, Jalgaon and Hiwarkhed, where the rates are below the average rate of the other town circles in the districts. The percentage of males to females born was 105·2, ranging from 106·9 in Buldana to 104·1 in Ellichpur. The greatest numbers of births were registered in the months of March, October, August and September, the least in January, June and May.

The number of deaths recorded in 1895 was 141,937, or 22,376 more than in the previous year. The increase was mainly due to cholera, dysentery and diarrhœa, which, together, accounted for an increase of 18,033 deaths. The death-rate, which has been exceeded only twice, in 1878 (81·5) and 1883 (51·3) during the last 28 years, was 49·9 per 1,000 of the population as compared with 42·0 in 1894, and 35·4 the quinquennial mean. The highest death-rates, 58·4 and 55·3 per 1,000 were recorded in Basim and Buldana, where the incidence of cholera was most severe. The lowest district death-rate was 41·6, registered in Wun. In only one of the 67 rural circles was the registered mortality below 30 per 1,000, in eight it was between 30 and 40, in 25 between 40 and 50, in 20 between 50 and 60; while in 13 it was between 60 and 73·1. In each of these 13 circles the excessive death-rates were due to cholera. The average death-rate in rural circles, which was 50·4, exceeded the average rate in the towns by 4·0 per 1,000. Only in Wun, where the two towns suffered much from cholera, was the urban death-rate higher than the rural. The highest death-rates in the towns were 76·0, 69·2 and 68·4 per 1,000 recorded respectively, in Digras, Pusad and Deulgaon Raja, but in 11 others the rates were between 53 and 60 per 1,000. The excess of mortality in these towns was due to cholera, or to both cholera and fevers. The lowest rates were 35·5 registered in Akola, and 32·9 in Mangrul Dastgir.

In every district the male death-rate was higher than the female, the provincial average having been 111·6 deaths among males for every 100 among females, while in the districts the percentages ranged from 121·1 in Wun to 106·7 in Buldana. In the towns there were greater differences, *e.g.*, 186 in Yeotmal, 143·8 in Pusad, and 136·5 in Amraoti, compared with 97·7 in Talegaon, 95·5 in Anjangaón, and 93·1 in Wadegaon. In the last three towns more female children were born than males, which, Dr. Little considers, may, in a measure, account for the higher female death-rate. The mortality in the third quarter of the year (18·2 per cent. of the total) was more than twice as great as the mortality in the first (8·6), the mortality in the second (11·2), and fourth (11·9), being about equal to each other. The largest number of deaths (19,722) was registered in August, and the smallest number (7,685) in January.

Among infants the death-rates per 1,000 living were, among males 310·5, and among females 276·4. Boys between one and five years of age died at the rate of 122·8 per 1,000, and girls at the rate of 109·3. From five years to ten years the male rates continued higher, but not until the age-periods above 40 were they again higher than the female rates.

The mortality among the 492 Native Christians in the province was at the rate of 73·1 per 1,000; among "other classes" the death-rate was 56·5, among Hindus it was 50·1, and among Muhammadans 43·9.

The total number of the population of Madras Presidency, among whom vital statistics were recorded in 1895 was 33,605,784, according to the census population, or about two and a half millions less than the estimated population. In some hill districts, zemindaries and certain islands on the west coast, inhabited by a population of 2,036,044, registration is not yet carried out.

The total number of births registered was 976,572, equal to a birth-rate of 29·1 per 1,000 of the census population as compared with 27·7 in 1894, and 26·7, the mean of the previous five years. The highest birth-rate recorded among the districts was 38·4 in Chingleput; the lowest 17·3 in Ganjam. The average birth-rate of the rural circles was 28·7 per 1,000 as compared with 33·6, the average of the town cirles. The highest rates obtained in town circles were 53·0 per 1,000 at Vaniyambadi in Salem, 48·8 in Kayalpatnam, and 46·2 in Sivakasi, both in the Tinnevelly district; the lowest rate was 7·1 recorded in Samalkot, in Godaveri. In Madras town the rate was 42·5. The provincial Sanitary Commissioner states that a good deal of improvement in the accuracy of registration in municipalities has been effected by a procedure devised for the better checking of the results of compulsory vaccination. Under this system each infant born is identified with a number, and by means of special registers its history is followed until it has been vaccinated. It has been discovered that the municipal subordinates, in order to obtain or manitain a reputation for the discovery of unrecorded births, recorded births that never took place. Dr. King does not think this practice is widespread, as it can only exist in places where pressure to obtain favourable results is put on unscrupulous subordinates, without sufficient care being taken to check their reports. The percentage of male to female births was 104·3, ranging from 108·9 in Ganjam to 108·8 in Kurnool.

The total number of deaths recorded was 658,719, and the death-rate was 19·6 per 1,000 as compared with 20·0 in 1894, and 20·6, the mean ratio of the previous five years. Among the districts the rates ranged from 25 per 1,000 in Tinnevelly to 13·6 in Ganjam. The average rate obtained in rural areas was 19 per 1,000 as compared with 27·2 in the towns. Among the latter the highest rates were recorded in Kayalpatnam (42·9), Madras (38), Sivakasi (37), and Tenkasi (36·3). In 13 towns rates under 12 per 1,000 were recorded, including Shendamangalam (9·1), Tiruvannamalai (8·4), Pithapuram (7·7), Ambur (6·1), and Sainalkot (5·7). The greatest mortality occurred in December, the least in April. For every 100 female deaths recorded there were 104·8 male deaths.

Among infants under one year of age the death-rates per 1,000 living were, males 150·2 and females 123·3. Among boys and girls between one year and five years of age the death-rates were, respectively, 24·2 and 22·2 per 1,000. In the age-period 10 to 14 the female death-rate was slightly higher than the male, and between the ages of 15 and 29 the female rates were considerably the higher. At all other periods the male rates were the higher.

Among the various classes the highest death-rate, 19·9 per 1,000, was registered among Hindus, and the lowest, 9·5 among the comparatively very small population of "other classes," while Muhammadans, 17·2, and Native Christians, 15·6, occupied intermediate positions.

The population of Coorg consisted at the time of the census of 1891 of 95,907 males and 77,148 females. In 1895 the number of births recorded was 4,567, equal to a birth-rate of 26·39 per 1,000 as compared with 26·43 in the previous year, and 19·89 the quinquennial mean. In rural circles the average rate was 27·48 as compared with 15·28 in the towns. The number of males born for every 100 females born was 99·69, but in the towns, which are very small, there were great differences in the proportions of the sexes born.

The total number of deaths registered was 5,073, an average of 29·31 per 1,000, as compared with 24·59 in 1894, and 25·61, the average of the previous five years. The average death-rate in rural circles was 28·77, as compared with 34·88 in the towns. June was, as usual, the month in which the greatest number of deaths was recorded; the smallest number was registered in January. Among infants under one year of age, the death-rates per 1,000 living were 287·88 for males, and 253·06 for females. Boys between one year and five years died at the rate of 35·22 per 1,000, and girls at the same ages died at the rate of 30·82. In the age-periods between five and 30, the female death-rates were the higher. The lowest death-rate was registered among the Muhammadans, 25·74 per 1,000, the Hindus following with 29·47, and "other classes" with 35·24.

In the Bombay Presidency, the village registers are examined by the Vaccinators, whose duty it is to report any discrepancies they may discover to the Deputy Sanitary Commissioner of the registration district. This system is reported to render results more accurate, but it is feared that it may damage the cause of vaccination If a Vaccinator is too zealous in his scrutiny of the registers, he embroils himself with the

village headman, and it is on the goodwill of the latter that much of the success in obtaining children to be vaccinated depends.

In the Presidency, including Sind, there were 674,304 births registered, or 14,036 in excess of the number recorded in 1894. The birth-rate was 35·83 per 1,000 of the population, against 35·08 in the previous year, and 36·04, the mean of the previous five years. In the Western, Central, Southern, and Gujarat Registration Districts the birth-rates were higher than in 1894; in Sind (24·98), where registration is particularly defective, there was a decrease of nearly 2 per 1,000. In only two collectorates were the ratios over 45 per 1,000—Ahmednagar 47·66 and Khandesh 45·65. In six others the rates were over 40·0. The lowest rate in any collectorate, except 19·07, registered in the city of Bombay, was 19·32 per 1,000, registered in Hyderabad. The average recorded birth-rate in rural circles was 36·78 against 29·04 in the towns. Among the latter, the rates ranged from 57·99 in Athni to 17·53 in Nasik. In four other towns, Borsad, Sangamner, Ahmednagar, and Vengurla, the rates were over 55 per 1,000, in four others besides Nasik, namely Bombay, Jacobabad, Mahad, and Thana, the rates were below 20. In the Presidency generally the percentage of male to female births was 108, but in the Sind district the percentages varied from 117·41 in Karachi to 131·86 in Hyderabad. The largest number of births were registered in the months of July, October, August, and June, in order, and the smallest number in February. The smallest number of births was registered in February 1894 also, and in this month the lowest average has been recorded during the previous 10 years.

There were 538,540 deaths registered, equal to a death-rate of 28·61, as compared with 32·26 in 1894, and an average of 29·48 during the previous five years. There was a decline in the death-ratios in each of the registration districts, and in the case of Gujarat this decline was enormous. In that registration district, the recorded death-rate in 1895 was only 26·89, against 42·35 in 1894, and 34·48, the average of the previous 10 years. The falling-off was conspicuous in every collectorate of the district, but no explanation is given by the local Sanitary Commissioner. In only five collectorates in the Presidency, viz., Ahmednagar, Sholapur, Satara, Belgaum and Thar, and Parkar, were the death-rates in 1895 higher than the rates obtained in 1894. In rural circles, the average death-rate in 1895 was 28·26 per 1,000, against 31·98 in 1894; in the towns, the average death-rate was 31·18 against 34·27. In five towns the death-rates were in excess of 45 per 1,000, namely, Pandharpur, 69·86, Ahmednagar 54·26, Sangamner 50·45, Sholapur 47·98, and Barsi 46·95; in the remaining 51, the rates ranged from 38·47 in Nasik, to 15 in Mahad.

On page 18 of his report, the Sanitary Commissioner, Bombay, has arranged the 56 towns in two parallel columns. In the one column the towns are arranged in the order of the birth-rates from the highest to the lowest; in the other a similar arrangement is determined by the death-rates. If a line is drawn through the middle of both lists, it is found that in 28 of the towns the birth-rates were 33·67 per 1,000 or less, and in a like number the death-rates were 29·26 or less. But the towns in the lower division of each column do not correspond; 11 towns, in which the death-rates were over the average, show birth-rates under the average; for example, in Nasik, one of the highest death-rates in the Presidency was recorded (38·47), and the lowest birth-rate of any. It is commonly found in India that births are more likely to escape registration than deaths, but, just as there were 11 towns in which the death-rates were above the average and the birth-rates were below it, so there were, of course, 11 towns in which the birth-rates were above the average and the death-rates below it; for instance, in Gadag-Bettigeri, the birth-rate was 46·56 per 1,000, and the death-rate only 25·86. In some cases, were the birth-rates were low, and the death-rates comparatively high, a considerable deficiency of female population may be the cause. This is the case in Bombay, where, however, the recorded birth-rate calculated on twice the total female population is less than 26 per 1,000. In the other class of cases, where the population is considerable, and the excess of births over deaths is great, both rates being low, it is almost certain that registration is bad, and in such cases the cause should be readily detected and a remedy applied.

Among male infants, the death-rate per 1,000 living was 191·04, and among females 161·92; among boys between one year and five years of age, the death-rate was 53·56, and among girls 50·99. As in 1894, in the age-periods from five to 40, the female death-rates were the higher, over 40 the male death-rates were the higher.

The death-rate among Hindus was 30·87, among Christians and Muhammadans, the rates were in each class 20·55, and among "other classes" 13·88 per 1,000. The highest mortality, as in 1893, occurred in August, and the lowest in February.

The area under registration, which comprises the whole of Lower Burma, except the districts of Northern Arakan, Salween, and portions of the districts of Bassein, Toungoo, and Thayetmyo, with a total population, according to the census of 1891, of 4,516,599, remained unchanged, although alteration in district areas resulted from the breaking up of the Schwegyin district, and the formation of a new Thaton district.

The total number of births registered in 1895 was 131,147, equal to a birth-rate of 29·04 per 1,000 of the population, as compared with 27·62 in the previous year, and 24·48 the quinquennial mean. Although the rate obtained in 1894 was the highest recorded, and the rate for the past year is still higher, there is obviously much room for improvement in registration. As instances of the neglect of registration, the Civil Surgeon of Pegu, while on tour in the district, discovered that the foils relating to 1,072 births and 864 deaths, which had been made over to the police by the village headman, had not reached the office of the Deputy Commissioner; in the Shanywa village the Civil Surgeon saw at least 50 children under one year of age, but only 10 births had been reported; in Tharrawaddy the foils were not regularly collected owing, in some cases, to the neglect of the constables, and in others, to the village headmen not leaving the foils in the custody of responsible persons during their absence from their villages. The highest district birth-rates were 38·79 per 1,000 recorded in Sandoway, 34·94 in Tavoy, 33·34 in Mergui and 32·14 in Pegu, and the lowest rates were 25·41 per 1,000 registered in Toungoo, 24·40 in Thongwa, and 22·88 in Amherst. The average rate in rural circles was 29·71 per 1,000, as compared with 24·42 in the towns. The highest urban rates were 99·95 per 1,000, recorded in Letpadan, 52·25 in Zigon, and 49·18 in Thonze, all three small towns in the Pegu district. In Mergui a rate of 43·11 was registered, and in Myaungmya 40·63. The lowest rates were 11·56, recorded in Kyaukpyu, and 11·66 in Ramree. Although in Bassein the birth-rate was 30·09 per 1,000, in the other large ports the birth-rates were, as usual, very low, 18·33 in Rangoon, 19·03 in Akyab, and 21·91 in Moulmein. This is, no doubt, due in some measure to the excess of males among the population, but other causes are at work, as the birth-rates were not low in proportion to this excess, *e.g.*, in Bassein, the proportion of females to males is lower than in Moulmein. Considerable fluctuations in the percentage of males born to females were observed in the various districts; the average was 107.

The number of deaths recorded was 101,160, or an average of 22·40 per 1,000 of the population, as compared with 23·56 in 1894, and 19·73, the mean of the previous five years. This figure, although it has been exceeded only twice, is obviously very much below the true death-rate. The highest district death-rates were 31·27 and 26·54, registered, respectively, in Akyab and Thayetmyo, while the lowest was 15·88 recorded in Amherst. The average rate in the rural areas was 21·69, against 27·27 in the towns. The highest rates recorded in the towns were 58·58 registered in Letpadan, 45·75 in Myaungmya, and 44·31 in Thonze; in the remainder, with the exception of Gyobingauk, where the very low rate of 9·64 was recorded, the rates varied between 40·83 in Allanmyo and 13·59 in Schwegyin. The heaviest mortality occurred in July and August, and the least in March and February.

Among infants under one year of age the death-rate per 1,000 living among males was 208·37, and among females 150·71; among boys and girls over one year and under five years of age, the ratios were 33·31 and 28·61; at all age-periods, except those from 20 to 40, the male death-rates were the higher. For every 100 deaths of females, the deaths of 121 males were recorded. Among the various sects, by far the lowest death-rate was that of the Christians, 11·19 per 1,000; this was followed by 20·99 among Hindus; 21·39 among "other classes"; 22·68 among the Burmese or Buddhists; and 23·26 among the Muhammadans.

History of Chief Diseases.

Cholera.

The total number of deaths registered in 1895 as due to cholera, throughout India and Burma, was 320,979, against 529,049 in 1894, and 217,507 in 1893. As compared with 1894, there was a great fall in the mortality from cholera in Madras, Bombay, Bengal, and the North-Western Provinces and Oudh, while in the Central Provinces and Berar the rise was as notable. In the Punjab, the number of deaths rose from 113 in 1894, to 549 in 1895, and in Rajputana, from 2 to 1,049. In Assam, Central India, and Mysore, the numbers of deaths were much greater than in 1894, and in Hyderabad much less. In Ajmere-Merwara, where no death was registered in 1894, there were 289 in 1895, while in Coorg, where 8 deaths were recorded in the former year, no death was recorded in the latter.

In the following statement, the numbers of deaths registered in the various provinces in 1895 are compared with the numbers registered in the preceding 18 years:—

Statement showing the Deaths from Cholera in the different Provinces in India from 1877 *to* 1895.

In the next table the mortality in each province in 1895 is compared with the mean mortality of the previous five years, 1890–94; the deaths registered in urban and rural circles are placed side by side; the percentages of villages attacked are shown;

the maximum mortality in rural and urban circles are contrasted, and the months of maximum prevalence in each province are indicated :—

Province.	Mortality in 1895.	Mean Mortality of previous Five Years.	Urban Mortality.	Rural Mortality.	Per cent. of Villages attacked.	Maximum Mortality in any one Rural Circle.	Maximum Mortality in any one Town.	Month of Maximum Prevalence.
Bengal - -	2·49	2·82	3·64	2·43	10·7	7·01	16·07	December.
Assam - -	3·78	3·83	4·72	3·76	15·8	8·32	22·89	May.
North-Western Provinces and Oudh.	1·10	2·73	0·66	1·15	5·8	7·54	8·20	May.
Punjab - -	0·03	0·88	0·01	0·03	0 2	0·54	0·37	May.
Central Provinces -	1·63	1·56	2·33	1·57	4·9	8·00	20·14	August.

Ajmere-Merwara -	·53	1·21	0·31	0·60	6·6	4·19	0·73	June.

The mortality ratios of this table are per 1,000 of population.

The number of deaths ascribed to cholera in Bengal in 1895 was 177,087, and the death-rate from this cause was 2·49 per 1,000 of the population, as compared with 3·32 in 1894, and 2·82 the average of the previous five years. The disease was present in every district during the year, although the mortality in the different districts varied greatly; in four districts, namely, Dacca (where the death-rate was 7·08 per 1,000), Faridpur (6·03), Nadia (5·36), and Jessore (5·35), the death-rates were over 5 per 1,000; and in four, namely, Saran (·26), Singhbhum (·23), Darjeeling (·15), and Lohardaga (·03), the rates were below 0·5 per 1,000. In the rural areas the average death-rate was 2·43, against 3·64 in the towns. Among the latter, the death-rates were highest in Kotrung, a small town in the district of Hoogly (16·07), Narayanganj, in Dacca (14·56), Kishorganj, in Mymensingh (13·36), and Ranaghat, in Nadia (12·22). In only 9 of the 147 towns was there no cholera death recorded; these were Dumraon, Revelganj, Lalganj, Chatra, Lohardaga, Daltonganj, Darjeeling, and Kurseong. Of these towns, Dumraon, with 18,384 inhabitants, is the largest. None are in the endemic area proper, and only three of them are on alluvial soil. In the province as a whole, the mortality was greatest in December (·48 per 1,000), April (·47), and November (·37), and least in February (·07) and September (·08). The least mortality occurred at the time that the rainfall was heaviest. This relation to the rainfall was, however, confined to Bengal proper, which on account of its preponderating population must, ordinarily, determine such statistics when the province is taken as a whole. In Bengal proper, the largest numbers of deaths occurred in December (·84), April (·82), and November (·57), while the smallest numbers occurred in August (·03), July (·04), September (·04), and June (·06). In Bihar, where the heavy falls of rain come somewhat later, the months of heavy rainfall were the months when the mortality was highest, August (·36), June (·22), July (·17), and September (·14), while the months when the death-rates were lowest were February (·002), January (·02), and March (·02). In Orissa and Chota Nagpur, the relation of death-rates to rainfall is less apparent. In Orissa the heaviest mortality occurred in November, October, and July; in Chota Nagpur the heaviest mortality occurred in April and May. In Orissa the least mortality was recorded in the months of May, January, and February, in Chota Nagpur the fewest fatal cases occurred in January and December, but in February, March, and November the rates were low.

Regarding means of prevention Dr. Dyson writes :—

"Filtered water-supply schemes are, of course, out of the question in small towns and villages, but I should like to see sanitary wells provided, by which I mean wells properly covered over so as to prevent the possibility of pollution, and provided with pumps, which should at first be worked for the convenience of the people at certain hours of the day by men specially employed for the purpose. These wells should, for the present, be provided by, and worked at the expense of, municipalities and district boards—one or two in each town and one in each selected village will be enough to begin with. At first there might be some caste and other prejudices against the use of the wells, but these would soon give way especially in times of epidemic when the people saw the advantage of the sanitary well water over that of unprotected sources, and the comparative immunity which it conferred upon those who used it. By such object lessons, I feel sure that the use of suspicious tank or well water would gradually be discarded in favour of the sanitary well, which the people would then, probably, provide for themselves."

These proposals have, at any rate, the merit of being practical.

The total number of deaths ascribed to cholera in Assam was 18,962, and the death-rate from this cause was 3·78 per 1,000, which, although much higher than the rate registered in 1894, which was 2·69, is less than the quinquennial mean, 3·83. Except in Nowgong, where the unusually low death-rate of ·91 per 1,000 was registered, the mortality from cholera was very severe in all the districts of the Brahmaputra Valley, ranging from 8·14 in Kamrup, to 5·40 in Lakhimpur, and 3·93 in Sibsagar. In the Surma Valley districts of Cachar and Sylhet, the death-rates were respectively 2·57 and 2·06, while in the selected areas in the Khasi and Jaintia hills the rate was ·71 per 1,000. The average death-rate in the districts, excluding the towns, was 3·76 per 1,000 In the tea gardens, where the sanitary condition of the labourers is generally well looked after, and the water-supply is often well protected, the average death-rate among the coolies was 4·60 per 1,000; in every district the death-rates among the tea garden coolies were higher than those ruling among the outside civil population. Dr. Stephen attributes this to the disease being introduced from time to time from outside by new comers. Assuming that cholera deaths among the outside population are as carefully recorded as they are in the tea estates, no further explanation of the greater mortality among the coolies seems to be required than that they, in their close communities, suffered more than they would if they dwelt scattered over a wide tract of country. In the towns the average mortality, 4·72 per 1,000, was considerably higher than the average among the tea garden populations. In Nowgong, and in the small town of Jowai, in the Jaintia hills, no death from cholera was recorded, and in Shillong there was only one, while in the small town of Mangaldai, 16 deaths yielded the enormous death-rate of 22·89 per 1,000. In the other towns, the death-rates ranged from 13·46 in Tezpur to 1·85 in Barpeta.

As in previous years, cholera was present in every district of the Surma and Brahmaputra Valleys in every month of the year. The mortality was greatest in May, December, June, November, and April in the order given. The pre-eminence of these months was due in April, May, and June to heavy mortality in Kamrup, in November to great prevalence of the disease in Goalpara, and, in December, to a severe outbreak in Sylhet.

The total number of deaths registered as due to cholera in the North-Western Provinces and Oudh was 51,562, equal to a death-rate of 1·10 per 1,000 of the population; this, though much lower than the death-rate of 1894, and the quinquennial mean, which were 3·80 and 2·73 respectively, is higher than seven of the death-rates recorded in the past 14 years. Among the districts, the highest mortality was 7·56 per 1,000 recorded in Hamirpur, followed by 5·51 in Fyzabad, 4·35 in Basti, 4·21 in Sultanpur, 2·85 in Gonda, 2·53 in Rae Bareli, 2·42 in Azamgarh, and 2·08 in Shahjahanpur. In Partabgarh, Benares, Mirzapur, Jaunpur, and Bijnor, the rates varied between 1·72 and 1·11. In the remaining districts, there was but slight mortality from the disease, and the hill tracts were absolutely free from it. In the rural areas, the average millesimal death-rate was 1·13, against ·65 in the towns. Of the larger towns, high rates were recorded only in Fyzabad (5·83) and Shahjahanpur (3·75). The smaller towns, however, suffered more severely, among them, Rath in the Hamirpur district, with a death-rate of 8·20 per 1,000, Ahraura (6·79), and Chunar (3·50), in Mirzapur, were most affected.

The most notable feature of the seasonal distribution of the disease was its unusual prevalence in January, when 2,839 deaths were registered, the highest number ever recorded in this month. The number of fatal cases fell to 383 in February, to rise to 1,207 in March, 7,864 in April, and a maximum of 8,734 in May; the number of deaths again fell to 4,111 in June and continued to fall until August; in September the number of deaths began to rise again, and the rise continued till November, when 7,295 deaths were registered; in December the number declined to 6,726.

Both the Hardwar and *Magh mela* fairs were free from any outbreak of epidemic disease.

There were 549 deaths registered as due to cholera in the Punjab in 1895, and the death-rate was ·03 per 1,000 as compared with ·005 in the previous year, and ·88 the quinquennial mean. The disease was practically confined to the districts of Umballa and Karnal, where 511 and 31 deaths, respectively, were recorded; there were 4 deaths in Peshawar, and one each in Delhi, Jhang, and Rawalpindi. The urban death-rate was ·01 per 1,000; only 12 deaths were recorded in the towns, 10 in Umballa and one each in Deli and Rawalpindi. There were 3 deaths in the province in January, 168 in

May, 103 in June, 157 in July, 83 in August, 28 in September, 6 in October, and one in November. In the last three months all the deaths were registered in Umballa.

The number of deaths ascribed to cholera in the Central Provinces in 1895 was 15,506, and the death-rate was 1·63 per 1,000, against ·74 in the previous year, and 1·56 the quinquennial mean. Every district in the province was affected; in Nimar, Narsingpur, and Chanda, the death-rates were respectively 7·37, 5·96, and 5·42 per 1,000; in both Murwara and Sambalpur the rates were only ·01; in the remaining districts they varied between 3·77 per 1,000 in Betul, and ·04 in Balaghat. In the rural areas the average death-rate was 1·57 per 1,000, as compared with an average of 2·33 in the towns. Thirty-two of the 72 towns escaped altogether, and in a good many the death-rates were low, but some towns suffered very severely, among them, Badnur (20·14), Lakhnadon (18·79), and Bhandara (15·81), had the highest death-rates. Deaths occurred in every month of the year; the disease was most prevalent in August, September, and June; least so in January, February, and December.

The number of deaths from cholera in Berar was 11,919 or 4·2 per 1,000 of the population, against 3,452 or 1·2 per 1,000 in 1894, and an average death-rate of 1 per 1,000 in the previous five years. Among the districts, the highest-rate was recorded in Basim, 10 per 1,000. The Sanitary Commissioner notes that in epidemic years this district suffers specially severely. "Why this should be it is difficult to explain. The "local sanitary conditions of the villages in the Basim district are, if anything, better "than those of the other districts of the province, so that local insanitary conditions do "not account for the comparative relative intensity of cholera epidemic in the district." Next to Basim came Buldana, with a death-rate of 5·8 per 1,000. In the other districts the rates ranged from 4·5 in Wun to 1·4 in Ellichpur. Of the 67 rural areas only one escaped, the Chandur circle, "the sanitary condition of which is perhaps "worse, and certainly not better, than many of those which suffered." The average death-rate in the rural areas was 4·3 per 1,000, against 3·2 in the towns. Of the 37 towns only 11 escaped, among the latter Sendurjana, Pusla, and Burroor, in which, in 1894, the cholera death-rates were respectively 18·9, 15·8, and 10·3 per 1,000. "This, "it is possible, may have been only a coincidence, or it may be that these towns had been "rendered immune or less liable to attack by the epidemic prevalence of the previous "year." In eleven towns the death-rates were higher than the provincial average, and in five the rates were over 10 per 1,000; these were Digras (14·9), Akot (12·6), Pusad (11·7), Bulgaon (11·4), and Umerkhed (11).

The disease was prevalent in every month of the year, and, except in October and November, the numbers of deaths were above the average. The peculiarity of the seasonal distribution of the disease was the unusual numbers of deaths which occurred during the early months of the year.

The number of deaths recorded as due to cholera in Madras was 21,172, and the death-rate was ·6 per 1,000, as compared with 1·3 in 1894 and 1·7 the quinquennial mean. Three of the districts, Godaveri, Kistna, and the Nilgiris, are reported to have been entirely free from the disease, while in four districts, Madura, South Arcot, Tinnevelly, and Tanjore, deaths occurred during every month of the year. The highest death-rates were 2·4 per 1,000, recorded in Tinnevelly, 2·0 per 1,000 recorded in Bellary and in South Arcot, and 1·9 per 1,000 recorded in Coimbatore. In the rural areas the average death-rate was ·6 per 1,000 compared with ·8 in the towns. Of the 92 towns 42 escaped the disease, and in 23 of the remaining 50 the rates were lower than the provincial mean. In some of the towns the mortality was very heavy, especially Ramnad (12·1), Chidambaram (11·6), Tenkasi (9·4) Periyakulam (7·0) and Kalladakurchi (6·8).

The largest number of deaths were registered in January, July, and February, the least in December, October, May, and November.

Although the number of cholera deaths in Coorg is rarely considerable, not a year, since 1886, has passed without some deaths occurring, except in 1895, when there was none; in the year before there were 8, and the quinquennial mean is ·10 per 1,000 of the population.

The total number of deaths recorded as due to cholera in Bombay in 1895 was 8,890, or ·47 per 1,000 of the population, as compared with 1·78 in the previous year, and 1·24, the average of the previous five years. As in 1894, the population of the districts in Sind enjoyed complete immunity from the disease; in Broach there was only one fatal

case, and in Surat only 5. In the remaining districts the rates ranged from 1·52 per 1,000 in Sholapur to 0·01 in Surat. The average death-rate in the rural areas was ·48 per 1,000 against ·44 in the towns. Rather more than half the towns escaped the disease, and in 14 others there were less than 5 cases. Some of the towns suffered severely; among them Pandharpur, where the death-rate was 17·24 per 1,000. In recent years but little has been done to improve the sanitary state of this town, the energies and money of the municipality being devoted to the construction of a high school and the building of a bridge. The Deputy Sanitary Commissioner writes :—

"The proceeds of the tax levied on pilgrims is spent on things which will not in any way benefit them, such as a large high school while nothing is being done to improve the water-supply, which during the July fair was in a very unsatisfactory state, there being but little water in the tank above the intake, and what there was being undrinkable; in addition very little is being done to improve the sanitary condition of the town, drainage works are almost at a standstill, while there is very much to be done. In my opinion the spending of the pilgrim taxes should be entrusted to a provincial committee and not to the municipality."

A very high death-rate, 8·79 per 1,000, was recorded in the town of Ranebennur, in Dharwar, and a rate of 4·54 in Gokak, in Belgaum.

There were only 37 deaths in the Presidency in January and 19 in February, in March there there 30, and in April 140, after that the mortality steadily increased to a maximum of 1,652 in August; there was a considerable falling off in the numbers of deaths in September and October, but in November the total again rose to 1,485, to fall to 609 in December.

The number of deaths ascribed to cholera in Lower Burma was 5,150, and the death rate 1·14 per 1,000, as compared with 1·64 in 1894, and ·87, the average of the previous five years. No district entirely escaped, but in two, Tharrawaddy, and Tavoy, there were only two deaths. The disease was most severe in the districts of the Arakan Division; in Akyab the death rate was 3·50 per 1,000, the highest rate in the province; in Sandoway, 3·16; and in Kyaukpyu, 2·23. The second highest district-rate was 3·29, recorded in Myaungmya, the newly-formed district in the Irrawaddy Division; the other districts in that division also suffered considerably, the death-rates having been 1·61 in Thongwa, 1·55 in Henzada, and 1·28 in Bassein. The only other considerable death-rate was 1·30, recorded in Mergui. The average death-rate in rural areas was 1·14 per 1,000, exactly the same as the average rate in the towns. Eleven of the 35 towns escaped altogether, among them Ramree and Gyobingauk, where the disease was specially severe in 1894. The highest rates were recorded in Myanaung (8·20), Allanmyo (5·44), and Akyab (5·32). The greatest number of deaths was recorded in July, and the least in February.

In the following paragraphs, compiled, for the most part, from the Cholera Registers of Regiments and Jails, are given certain facts relating to the occurrence of cholera among European and Native troops, and among prisoners.

Cholera appeared on 20 occasions among 17 bodies of European troops; there were 47 seizures altogether, and 35 deaths, a case-mortality of 74·47 per cent. In 13 instances there was only one case among the body of men attacked, 10 of these single cases were fatal, and in connection with the three that recovered, it may be noted that there was no cholera in their neighbourhood at the time. In only two instances were there more than four cases—in the Highland Light Infantry at Fyzabad, 16, and in various corps at Secunderabad, where seven men were attacked in April and May.

Among Native troops, cholera occurred in 24 stations, among the men and followers belonging to 30 different corps. In four regiments the disease appeared on two separate occasions. There were in all 94 men attacked, of whom 69, or 73·4 per cent., died. In 18 instances only one man was attacked, and in only six were there more than four cases.

Cholera occurred in 43 jails on 46 occasions. There were 142 cases and 89 deaths, equal to a mortality of 60·67 per cent. In 28 instances, one prisoner only was attacked, and 18 of these died. In only nine instances were there more than four men attacked, including 14 at Dinajpur, 14 in the Deccan Convict Gang, and 13 at Sandoway.

Diarrhœa was specially prevalent at the time of the occurrence of cholera among European troops on only one occasion, and at the time of its occurrence among Native troops on two occasions. One of these was the outbreak at Malegaon, where there were 17 cases of cholera and seven deaths, a case mortality of about 41 per cent.

Diarrhœa was specially prevalent in four jails, just before, or at the time of, the occurrence of cases of cholera.

The following statement shows, as nearly as possible, the number of buildings occupied by the various bodies of men attacked, and the proportion of these in which cases of cholera occurred:—

Communities.	Number of Buildings occupied by Bodies of Men attacked.	Number of Buildings which furnished Cases.	Percentage.
European troops - - - - -	227	33	14·53
Native troops - - - -	11,814	80	·68
Prisoners - - - - -	500	86	17·2

The disease occurred at different stations under various many meteorological conditions, but it is not possible to connect the occurrence of the outbreak with these.

Among the troops, in many instances, the men are supposed to have contracted the disease in the *bazar*, or from *bazar* supplies, but in no instances in which the disease was reported to have been introduced in this way, and assumed an epidemic form, could any connection be clearly established between the first and subsequent cases. The disease was stated to have been imported into four jails, but in only one instance does the direct connection of the first with subsequent cases appear probable

In the following statement are shown the numbers of persons actually in attendance on cholera patients, and the percentage of those attacked:—

Communities.	Number of Cases of Cholera treated.	Medical Officers, Hospital Assistants, and other Attendants on Cholera Cases.		Percentage of Attendants attacked.
		Number.	Number of these attacked.	
European troops - - - -	47	200	—	—
Native troops - - - - -	94	345	5	1·45
Prisoners - - - - - -	142	321	11	3·42

Three of the five persons seized while in attendance on native soldiers were attacked during the outbreak in the detachment of the 9th Bombay Infantry, at Malegaon, where diarrhœa was very prevalent; all three recovered. In another case the attendant was attacked a few hours after visiting the sick.

Small-pox.

The deaths from small-pox in India in 1895 numbered 45,733, or 1,673 more than in the preceding year. But this increase was not general; it was limited to Bengal, the Punjab, the Central Provinces, and the small province of Ajmere-Merwara. The mortality was heaviest in Ajmere-Merwara, Assam, and the Central Provinces, and lowest in the North-Western Provinces and Oudh, and Coorg. The relative increase of the disease was most marked in the Central Provinces, where no less than 6,644 deaths were recorded in 1895, against only 1,500 in 1894.

As usual, in most of the provinces the disease showed signs of activity first in February or March, and again in December. More than one-half the total mortality of the year occurred during the months of March, April, May, and December.

The following table shows the prevalence of small-pox in the different provinces of India in 1895, month by month:—

Statement showing the Deaths from Small-pox registered in the different Provinces, by months during the year 1895.

Province.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total. 1895.	Total. 1894.	Ratio of Deaths per 1,000 of Population. 1895.	Ratio of Deaths per 1,000 of Population. 1894.
Bengal - -	611	923	2,163	2,642	1,798	1,195	944	515	421	357	556	895	13,020	8,404	0·18	0·11

The number of deaths recorded as due to small-pox in Bengal in 1895 was 13,020, or ·18 per 1,000 of the population. This rate, although it is insignificant when compared with the death-rates from other diseases prevalent in Bengal, is much higher than the death-rate of 1894, which was ·11 per 1,000, the lowest on record, and is considerably greater than the average of the ten years, 1885–94, which was ·15. There was a severe epidemic in Calcutta, where the death-rate was 3·25, the next highest district rate having been ·72, recorded in Faridpore. This district has been notorious for the opposition offered to vaccination by the people, headed by the influential sect of Ferazi Muhammadans. In order to overcome this, the provincial Sanitary Commissioner, towards the end of the year, sent one of his deputies, Dr. Deare, to the district. By his tact and perseverance, Dr. Deare has succeeded in winning over to a belief in the efficacy of vaccination, not only the Ferazi high priest, but most of the important religious leaders in Eastern Bengal, and, from October 1895 to March 1896, as many as 45,892 Ferazis were vaccinated. Death-rates over ·50 per 1,000 were recorded in Cuttack (·66), Howrah (·63), and Midnapore (·58), and in 13 districts the rates varied from ·38 to ·12; in Singhbhum there was no death; in the remaining 27 districts the rates ranged from 0·9 to ·002 per 1,000. The urban death-rate was ·91, as compared with ·14 in rural areas, and the towns showing the highest rates were North Dum-Dum in the 24 Parganas (3·65), Barnagore in the same district (2·21), and Birnagar in Nadia (2·04). Most of the high rates were registered in towns near Calcutta.

Although the number of deaths (6,631) among infants and children under 12 years of age was higher then in 1894 (5,652), the proportion per cent. of the total mortality (50·92) in 1895 was lower than in the previous year (67·25).

Among the European seamen in the port nine cases occurred, one of which was fatal, equal to a death-rate of ·69 per 1,000 against *nil* in the previous year, when only one man was attacked. Among the native floating population there were five deaths from small-pox, and the death-rate was ·19 per 1,000, as compared with ·03 in the previous year.

In Assam there were 3,849 deaths from small-pox registered during 1895, against 3,997 in 1894, and 2,021, the average of the previous five years. The death-rate was ·77 per 1,000, as compared with ·80 in the previous year. The highest district death-rate, 1·18 per 1,000, was recorded in Goalpara, where the disease was epidemic in 1893 and 1894. The Civil Surgeon of the district reports that the villagers persistently refuse to allow their children to be vaccinated. The next highest rate was 1·11 registered in Kamrup, mainly due to an epidemic in the town of Barpeta. In the other districts the rates ranged from ·96 in Sylhet to ·005 in Nowgong. The average rural death-rate was ·66 per 1,000, against 5·35 in the towns, where the number of deaths from small-pox rose from 61 in 1894 to 583 in 1895. Of the total, 483 were recorded in Barpeta, where the disease was introduced by a student who returned to his home from Calcutta. In Barpeta the last epidemic occurred in 1888, and as the

Mahapuryas, among whom the epidemic was almost entirely confined, refuse to accept vaccination, their children were quite unprotected. In Dibrugard, where the death-rate was 11·64 per 1,000, the first three cases of the disease were landed from a trading steamer from Calcutta. Vaccination is backward in this town, partly on account of superstitious opposition by the people, and partly on account of the floating nature of the population. In Sylhet, Dhubri, Nowgong, Shillong, Karimganj, Maulvi Bazar, Mangaldai, and Jorhat there was no death, and in the remaining head-quarter towns the rates ranged from 2·29 in Jowai, to ·18 in Gauhati and Goalpara. Among infants under one year of age there were 993 deaths, more than 25 per cent. of the total, and among children under twelve, 2,072 deaths, more than 53 per cent. of the total.

Up to 1892 the smallest death-rate from small-pox recorded in the North-Western Provinces and Oudh was ·16 per 1,000 registered in that year; in the following years the rate fell to ·13 in 1893, and 09 in 1894. In 1895 only 1,968 deaths were registered and the death-rate was ·04. No death was recorded in the district of Bijnor, and in 16 districts less than 10 deaths in each were registered. The highest district rates were 37, ·30, and ·27, registered respectively in Pilibhit, Kheri, and Jhansi. In only 27 among the 105 principal towns of the provinces did deaths from small-pox occur, and the urban and rural death-rates were practically identical. The highest ratios of mortality were recorded in Cawnpore ·35, Budaun ·20, and Kasganj ·19. Among infants under one year 580 deaths occurred, or about 29·5 per cent. of the total, and among children under 12 years of age 1,329, or about 67 per cent.

In the Punjab the number of small-pox deaths in 1895 was 8,334, against 6,068 in the previous year. The death-rate, which in 1893 was ·20 per 1,000, and in 1894 ·30, rose to ·41, or ·08 in excess of the quinquennial mean. The increase in small-pox mortality was due to an epidemic which began in the end of the year; the number of deaths, which had been 369 in October, suddenly rose to 949 in November, and to 2,088 in December. In four districts, Dera Ismail Khan (1·56), Hissar (1·52), Peshawar (1·33) and Gurgaon (1·06), the rates were over 1·0 per 1,000. In the remainder they ranged from ·94 in Umballa to ·001 in Gurdaspur. In the districts of Dera Ismail Khan and Peshawar the prevalence of the disease is ascribed to opposition to vaccination and to the operations of inoculators, and in Umballa to neglect of vaccination in small towns. In 12 of the towns, including Kaithal, Panipat, Jagraon, and Ferozepore, there was no death; in the others, death-rates ranged from 7·50 per 1,000 in Hansi, 5·28 in Peshawar, and 4·02 in Gujranwala, to ·01 in Amritsar. Among infants under one year of age 2,422 deaths occurred, or over 29 per cent. of the whole, and among children under twelve 5,244, or nearly 63 per cent.

The number of deaths from small-pox in the Central Provinces was 6,644, or ·70 per 1,000 of the population, as compared with death-rates of ·16 per 1,000 in 1894, and ·15, the average of the preceding five years. The death-rate of 1895 has been exceeded seven times in the last 22 years; in 1873 it was 1·37 per 1,000, in 1874, 2·38, and in 1875, 2·73; in 1878 and 1879 the rates were respectively 2·18 and 3·44 per 1,000, and in 1888 and 1889, 1·22 and 1·99. Not only was the disease more severe than in recent years, but it was very widely spread, as is shown by the occurrence of fatal cases in upwards of 85 per cent. of the registration circles. Among the districts the death-rates were highest in Nagpur (2·44 per 1,000), Jubbulpore (1·56), and Wardha (1·45). In Burhanpur only three deaths were recorded, in Nimar the death-rate (·08) was low, and in Mandla and Raipur the rates (·12 and ·15) were comparatively low. The average death-rate in the rural areas, ·58 per 1,000, was much less than in the towns, where the average was 1·96. In only 13 towns were there no deaths recorded, while in 16 death-rates over 3 per 1,000 were registered. The towns which suffered most were Tumsar (7·80), Charwa (6·71), Sindi (6·41), Harda (6·34), and Mohpa (5·68). The greatest number of deaths occurred in May, April, March, and June, in the order given. Of those who died, 2,019, or over 30 per cent. of the whole, were infants, and 2,964, over 44 per cent., children under 12 years of age.

In Berar the number of deaths recorded was 556, as compared with 1,061 in 1894, and the death-rate in 1895 was ·2 per 1,000, against ·3 in the previous year, and 1 the quinquennial mean. The highest district death-rates were ·4 in Buldana, and ·3 in Akola, and the lowest ·06 in Basim. Of the total number of deaths, 375 occurred in

rural districts, and 181 in the towns, in which the average death-rate was ·5 per 1,000. Among infants under one year of age, 205 deaths, or 36·9 per cent. of the total, occurred, and among children under twelve, 312 deaths, or 56·1 per cent.

The number of deaths from small-pox in Madras in 1895 was 5,111, and the death-rate was ·1 per 1·000 of the population, against ·3 in the previous year, and ·9 the quinquennial mean. The highest district rates were ·6 in Bellary, and ·5 in Anantapur. The lowest rate was ·006 recorded in the town district of Madras, where only three deaths occurred. In the Nilgiris also only one death occurred, but the rate was ·01 per 1,000. The next lowest rates were ·03, recorded in Coimbatore and in Malabar. As the latter district has been notorious for the prevalence of small-pox—the quinquennial death-rate is 2·6 per 1,000—the decrease in the mortality is the more gratifying. The death-rate in the rural areas was ·2 per 1,000, or just double the urban rate. The disease was present in the majority of towns, but the highest death-rates were only 1·6 per 1,000 recorded in Palkond, in Vizagapatam, 1·3 in Guntur, and 1·2 in Vellore. Of the fatal cases, 1,111, or 21·7 per cent. of the total, were infants, and 1,966, or 38·44 per cent., were children under 12 years of age.

In Coorg there were only seven deaths recorded, and the death-rate fell from ·21 in 1894 to ·04 in 1895, the mean ratio of the previous five years being 1·93. No deaths occurred among children under 12 years of age.

There were 2,299 deaths from small-pox in Bombay during 1895, and the death-rate was ·12 per 1,000 of the population, as compared with ·17 in the previous year, and ·15 the quinquennial mean. The disease was most severe in the collectorates of the Western Registration District, where the three highest death-rates were recorded, ·40 in Kolaba, ·37 in Nasik, and ·34 in Khandesh, and least severe in the collectorates of the Gujarat Registration District. In the Panch Mahal Collectorate there was no death, and in Kaira, Karachi, and Thar and Parkar the death-rates were only ·01 per 1,000. The average death-rate in rural areas was ·10, against ·25 in the towns, many of which escaped altogether. The death-rate in Alibagh, a small town in the Kolaba District, was very high, 5·95 per 1,000; a high rate of 3·34 was also recorded in Yeola, and comparatively high rates in Hyderabad (1·43) and Nandurbar (1·04). The number of infants that died was 613, or 26·6 per cent. of the total deaths, and of children under twelve 1,255, or 54·6 per cent.

There were 1,540 deaths from small-pox in Lower Burma during the year, and the death-rate was ·34 per 1,000 as compared with ·38 in 1894, and ·54 the mean of the previous five years. In the districts of the Arakan division there was only one death, in Akyab, and in Tenasserim there were only 28 deaths, of which 13 occurred in Mergui. There were 222 deaths in the Pegu Division, and 1,280 in Irrawaddy. In the last-mentioned division the death-rates were comparatively high in all the districts, ranging from 1·97 in Henzada to ·11 in Bassein. The disease has been prevalent in Irrawaddy for the last three years, the practice of inoculation is rife, and there is much opposition to vaccination. There was no death in 23 of the 35 towns; in Donabyu the death-rate was 4·00 per 1,000, in Zalun it was 2·33, and in Kyangin 1·11; in the remainder the rates ranged from ·97 in Kawkareik, to ·06 in Thayetmyo.

Among infants 348 deaths, or 22·6 per cent. of the whole, occurred, and among children under twelve 890, or 57·8 per cent.

Fevers.

The total number of deaths registered under the heading "Fevers," fell from 5,001,159 in 1894 to 4,266,293 in 1895. The decrease in mortality was specially notable in the North-Western Provinces, the Punjab, and Ajmere-Merwara, where the ratios fell to the extent of 8·57, 5·99, and 4·77 per 1,000 respectively. In only four provinces was there increased mortality; in Madras and Mysore the increase was slight, but in Assam and Coorg the millesimal ratios were respectively higher by 1·44 and 3·21. The provincial death-rates ranged from 23·48 in Coorg and 23·31 in the North-Western Provinces and Oudh to 8·3 in Madras and 7·67 in Mysore.

The minimum monthly death-rate was recorded in February, the rates rose till April to fall again in May and June; in the second quarter of the year the rates rose gradually, and in the last quarter rapidly to a maximum in December.

Statement showing the Deaths from Fevers registered in the different Provinces, by months, during the year 1895.

* Includes 15,894 deaths from Kala Azar.

† Includes 13,164 deaths from Kala Azar.

In Bengal the scheme for the sale of Government quinine through the medium of the Postal Department makes steady progress. The total number of post offices supplied with quinine increased from 2,321 in 1894 to 2,509 in 1895, the numbers of powders filled and packed during the year rose to 3,760,434 against 2,917,526 in the preceding year, and the amounts realised by the sale of pice packets aggregated Rs. 49,390 in 1895, as compared with Rs. 31,832 in 1894, and Rs. 18,047 in 1893.

The extension of the scheme to the North-Western Provinces and Oudh was sanctioned in December 1895 by the Government of India for all the districts in the Meerut Division, for the district of Pilibhit, and for the Tarai Perganas of Kichaha, Kilpuri, and Kashipur.

In Assam, from 1st October 1894 to 31st December 1895, quinine was sold through 137 post offices in the Brahmaputra Valley, and 82 post offices in the Surma Valley, and the total amount realised amounted to Rs. 703-14-0. In July 1896 the Government of India sanctioned the extension of the scheme to all post offices in Assam.

The number of deaths attributed to fevers in Bengal, in 1895, was 1,634,254, as compared with 1,799,833 in 1894. But although the death-rate of 1895, 22·99 per 1,000, exhibits a notable decrease when compared with that of the previous year, 25·32, it is considerably higher than the average of the five years, 1890–94, which was 20·81 per 1,000 of the population, and that again is higher than the average of the 10 years, 1885–94, which was 18·0. It is repeated that the serious progressive increase in the fever mortality in Bengal is due to the stoppage of natural drainage. However this may be, it is certain that the increase in mortality is generally distributed throughout the province: of the 46 districts, only two, Monghyr and Shahabad, show, in 1895, slight diminution in mortality, as compared with the average of the past 10 years; in each of the other 44, with the exception of Gaya and Noakhali, the increase is over 1 per 1,000, and ranges from 10·02 in Muzaffarpur to 1·34 in Murshidabad. These figures are the more significant of progression in the mortality, inasmuch as in 29 districts the mortality in 1895 is less than the previous year. The stoppage to natural drainage may be very largely responsible for augmented mortality, but unless such obstruction is general, it cannot alone account for so universal an increase. The districts which suffered most were Jessore (33·43 per 1,000 died), Dinajpur (32·83) and Jalpaiguri (32·56), while those which suffered least were Saran (13·89), Balasore (13·67), and Puri (6·92). The rural death-rate, 23·22 per 1,000, was, as might be expected, much higher than the urban rate, 18·43; both are lower than in 1894, when the rates were, urban 19·19, rural 25·63, but it is significant in connexion with the stagnation theory, that, while the urban rate is 6·14 per 1,000 higher than the decennial average, the rural excess is only 4·93. The highest urban

rates were 47·82 per 1,000, recorded in Chanduria, a small town in the Khulau district, 42·49 in Kumarkhali, a small town in Nadia, 39·01 in Malda, and 37·59 in Banshberia; the lowest rates were 5·73 recorded in Chapra, 6·76 in Jhalukati, 7·16 in Nalchiti, both small towns in Backergunge, and 7·95 in Tangail; in the remaining towns, the rates ranged from 36·53 in Birnagar, to 8·16 in Puri. The heaviest mortality occurred in the months of December, November, April, and January, in the order given, and the least in June, February, August, and March.

Under the heading "fevers" there were 92,359 deaths registered in Assam in 1895, and the death-rate, which was 16·95 per 1,000 in 1894, rose in 1895 to 18·39, or 2·21 per 1,000 in excess of the average of the previous five years. By far the highest death-rate was 37·17 per 1,000, recorded in Nowgong, where *kala-azar* is very prevalent; the next highest were 29·24 and 22·90, recorded, respectively, in Goalpara and Darrang. Excluding the selected areas in the Khasi and Jaintia Hills, the lowest recorded rates were 12·99 in Lakhimpur, 14·20 in Cachar, and 15·02 in Sylhet. In the rural areas, the average fever death-rate was 18 46, as compared with 15·49 in the towns. Among the latter, high rates were registered in Nowgong (37·18) and Mangaldai (35·77), and a very low rate in Shillong (3·42). In the remaining towns, the rates ranged from 24·87 in Golaghat, to 6·15 in Hailakandi. The greatest monthly mortality occurred in October, November, and December, and the least in February and March.

Kala-azar.—Regarding the distribution of this fatal form of fever the provincial Sanitary Commissioner writes:—

"There were 15,894 deaths reported from this disease in 1895, as against 13,164 in the previous year. As in 1894, there were a few *kala-azar* deaths reported from the Surma Valley and from the Sibsagar, Lakhimpur and the Khasi and Jaintia Hills districts, but almost all the deaths from this cause were registered in the Goalpara, Kamrup, Darrang and Nowgong districts. The disease is also still prevalent in the Garo Hills district. In the small portion of this district under registration, 38 *kala-azar* deaths were reported, as against 40 in 1894.

"In the Goalpara district there were 265 *kala-azar* deaths reported, as against 384 in 1894. Most of the deaths occurred on the left bank of the Brahmaputra river in the Goalpara and Salmara rural circles of registration. The disease is gradually disappearing from this district. In the Kamrup district the deaths fell from 2,149 in 1894 to 2,059 in 1895. The mortality from *kala-azar* in this district on the left bank of the river is diminishing gradually, but on the right bank, in the Barpeta and Nalbari rural circles, it continues to increase slowly. There were 2,477 *kala-azar* deaths registered in the Darrang district, as against 1,992 in 1894. Of the deaths registered, 2,405 occurred in the Mangaldai rural circle. The disease seems to be gaining a footing in the Tezpur circle.

"Of the 15,894 *kala-azar* deaths reported in the province, 11,037 occurred in the Nowgong district, being 2,452 more than the number recorded in 1894. Including deaths from *kala-azar*, there were 1,413 more fever deaths reported in this district than in 1894; but, excluding *kala-azar*, there were only 1,753 fever deaths reported, as against 2,792 in the previous year. It is not at all probable that the death-rate from malarial fevers in the Nowgong district was less than it was in the previous year, seeing that, in the neighbouring district of Sibsagar, the fever death-rate was nearly the same in both years. It is therefore highly probable that a considerable number of deaths which, in 1894, would have been returned as ordinary fever, were, in 1895, returned as *kala-azar*. I visited a large number of places in the Nowgong district during last touring season, and ascertained that the general opinion in most places was that *kala-azar* was distinctly less prevalent than it was in the previous year."

Owing to the very high death-rate from *kala-azar* in Nowgong, the continued prevalence of the disease in Kamrup, and its apparently increasing prevalence in the Mangaldai subdivision of the Darrang district, the Chief Commissioner applied to the Government of India for the services of an officer to make special inquiry into the nature of the disease. For this duty, Surgeon-Lieutenant L. Rogers was selected, and proceeded to Assam in April 1896.

In this Report for 1892, it was pointed out that the so-called *beri-beri* of coolies was not related to the disease of that name due to the manifestations of a specific peripheral neuritis, which is common in the Straits and Eastern Archipelago, and that the presence of the anchylostomum (*strongylus duodenalis*) although a possibly dangerous complication, was not the cause of the disease known as *kala-azar*, which, it was surmised, was probably related to malarial fever. So far, Dr. Rogers' investigations support these conclusions.

He finds that the anæmia of *kala-azar* differs from that of anchylostomiasis:—

(1.) In *kala-azar*, the hæmoglobin and the red corpuscles are nearly equally reduced; in anchylostomiasis, the hæmoglobin is reduced more than twice as much as are the red corpuscles.

(2.) In *kala-azar*, the proportion of white corpuscles to red is much reduced, except during the actual presence of fever, when there is a relative leucocytosis; in anchylostomiasis, the white blood-cells are relatively increased.

(3.) In *kala-azar*, the specific gravity of the blood is higher, relatively to the degree of anæmia present, than in anchylostomiasis.

In *kala-azar*, the degree of anæmia increases in direct proportion to the presence of fever, and to the height to which the temperature rises, the red corpuscles being destroyed, while the white cells seem to become gradually reduced in numbers. The bone marrow is found to be characteristically changed. A peculiarity of the fever of *kala-azar* is the comparative insensibility to its presence of the victims, who, when the temperature is as high as 103° F., will frequently deny that they have fever.

The number of deaths ascribed to fevers in the North-Western Provinces and Oudh in 1895, was 1,093,212, against 1,495,372 in 1894. The death-rate fell from 31·88 in 1894, to 23·31, as compared with 25·17, the quinquennial mean. The percentage of deaths described as having been due to fever was 80, but so many diseases are included that this figure is not of very great value as determining the mortality occasioned by malarial influences; and in 1895, many of the deaths were no doubt due to influenza, which was prevalent in several districts. Among the districts, the highest death-rates were registered in Kheri, 41·99, Naini Tal, including the Tarai, 40·06, Saharanpur, 39·23, and Pilibhit, 35·24; the lowest in Gorakhpur, 16·27, Rae Bareli, 15·59, and Partabgarh, 7·31. In the last-named the death-ratio under the heading "All other causes" was 10·4 per 1,000, as compared with the provincial average 3·11. In the rural areas, the average mortality was 23·20 per 1,000, against 24·79 in the towns. In only one of the larger towns, Muzaffarnagar (43·87), was the fever death-rate exceptionally high; but in some of the smaller towns, *e.g.*, Deoband (73·87), Gangoh (44·64), and Hapur (44·00), the mortality was very great.

"A very limited outbreak of typhus fever occurred in October in Kumaun and was investigated and reported on by Dr. Thorold. He came to the conclusion, which others have come to before, that defective ventilation and absolute absence of sanitation exist in nearly all these mountain villages. . . . . A slight outbreak also occurred in Garhwal."

There was a considerable reduction in the fever mortality in the Punjab, the number of deaths having fallen from 515,238 in 1894, to 392,118. The death-rate per 1,000 of the population was 19·08, against 25·07 in the previous year, and 26·81 the quinquennial mean. In 14 of the 31 districts, the rates were in excess of the provincial average, but in only two districts, Simla and Kangra, were the death-rates higher than the quinquennial mean. In most of the other districts, there was a considerable fall in the rates, as compared with the averages, and this was specially noteworthy in the district of Jhelum and in those districts lying between the rivers Jhelum and Sutlej. The highest death-rates were registered in Umballa (29·14), Kangra (24·37), and Kohat (23·85), and the lowest in Jhang (10·74), Shahpur (9·85), and Montgomery (9·26). In the rural areas, the average death-rate was 19·15 per 1,000, as compared with 18·03 in the towns. The highest rates among the latter were 29·20, recorded in Sonepat, and 26·94 in Jagadri; the lowest 9·28 in Chiniot, 9·13 in Jalalpur, and 7·78 in Ferozepore. In the other towns the rates varied between 24·78 in Delhi, and 10·06 in Ludhiana. The number of deaths in January was 37,246, the mortality fell to a minimum of 26,514 in March, rose till May to 35,520, when it gradually fell to 26,556 in August; it then rose steadily till December, when the maximum, 49,415 deaths, was reached.

In the Central Provinces the deaths from fevers numbered 221,418, or 17,133 less than in 1894. In that year, influenza was largely responsible for the high death-rates, and in 1895 this disease was also present in Saugor, Nagpur, and Bhandara, but it does not appear to have been very fatal. The fever death-rate, although it declined from 25·11 per 1,000 in the previous year, to 23·30, was considerably higher than the provincial mean, 20·92. The districts which suffered most were Nimar, death-rate 44·52 per 1,000, Saugor, 36·86, and Narsingpur, 32·16; while Chanda, 17·18, Raipur, 16·13, and Sambalpur, 7·67, were least affected. The average rural mortality was 23·68, as compared with 19·32 in the towns. Among the latter, the rates ranged from 57·35 per 1,000 in Charwa, and 41·51 in Rankheri, both small towns in the district of Hoshangabad, to 6·86 in Sambalpur town, and 3·51 in Narkher in the Nagpur district. The heaviest mortality occurred in the months of October, September, and November in the order stated, and the least in February.

The number of deaths from fevers in Berar, although less than in 1894, was unusually high; 66,203 deaths were registered, equal to a death-rate of 23·2 per

1,000, as compared with 23·6 in the previous year, and 17·7, the quinquennial mean. Among the districts, the rates ranged from 27·7 per 1,000 in Wun, to 21·2 in Amraoti, the average rural death-rate having been 23·3, against an average of 22·8 per 1,000 in the towns. Among the latter, the extreme rates recorded were 49·6 in Digras, in Wun, and 10·8 in the town of Karajgaon, in Ellichpur. Although the monthly death-rate followed the usual seasonal course, the highest having been registered in August and September, and the lowest in February and June, a remarkable feature was the occurrence of an exceptionally heavy mortality with an exceptionally light rainfall; ordinarily, when the rainfall is below the average, so also is the fever mortality, and *vice versâ*.

The number of deaths recorded as due to fever in Madras was 277,337, and the death-rate was 8·3 per 1,000, as compared with 8·0 in the previous year, and 7·8, the mean of the previous five years. In six of the districts, the death-rates were over 10 per 1,000, namely, the Nilgiris (19·2), Vizagapatam (18·2), Cuddapah (16·0), Kurnool (15·1), Madras Town District (14·2), and Ganjam (10·4). These figures are in fair agreement with the quinquennial averages, although in the Nilgiris and Vizagapatam, there is considerable increase, and in Kurnool, a decrease. In Vizagapatam, if these figures were correct, all the deaths, except 2·5 per 1,000, would be due to fevers, and in the Nilgiris, all but 5·7; in spite of the malarious character of these districts, this, as pointed out by the Sanitary Commissioner, is scarcely likely to be the case. The districts, whence the lowest death-rates were reported, were Tinnevelly (4·6), Anantapur (2·8), and Tanjore (2·3). The average mortality in rural areas was exactly the same as the average in the towns. In three towns, all containing more than 10,000 inhabitants, namely, Tadpatri in Anantapur, Dowlaishweram in Godaveri, and Rasipuram in Salem, no death from fever was recorded. In these towns, 486 of the total 501 deaths registered were returned under the heading "All other causes." In the remaining towns, the rates varied between 21·5 in Kampli in Bellary, and 0·5 in Viravanallur in Tinnevelly, and ·1 in Ramnad and Madura. The monthly mortality was fairly evenly distributed, but the death-rates in August, September, and December were highest, those in February and April lowest.

There were 4,064 deaths ascribed to fevers in Coorg, and the death-rate was 23·48 per 1,000 of the population, against 20·27 in 1894, and 19·52 in the five years preceding 1895. The rural rate was 24·20, against 16·12 in the towns. The heaviest mortality occurred in June and July, and the least in January, February, and March.

The total of deaths from fevers registered in Bombay was 388,848, which, although less by 40,246 than in 1894, is the highest recorded, except in that year and in 1892. The death-rate was 20·66 per 1,000, as compared with 22·80 in 1894, and 21·16, the quinquennial mean. Among the collectorates, the highest death-rates were recorded in Sholapur (30·75 per 1,000), Ahmednagar (28·33), and Satara (28·15), and by far the lowest in Ratnagiri (11·06), and Bombay City (7·86); in the remainder, the rates ranged from 27·39 in Khandesh to 14·89 in Kanara, and 13·35 in Hyderabad. The rural mortality was 21·36 per 1,000, as compared with 15·62 in the towns. Among the latter there were great divergences from the mean; the extremes were 40·67 in Barsi, a town of upwards of 20,000 inhabitants in the Sholapur district, and 6·05 in Junnar, a town of nearly 12,000 inhabitants in the district of Poona. In the cantonments of Deolali and Kirkee rates, respectively, of 4·79 and 4·91 per 1,000 were recorded. The heaviest mortality occurred in the months of August and December, and the least in February and June.

The number of deaths registered in Lower Burma under this heading in 1895 was 48,049, and the death-rate was 10·64, as compared with 10·65 in the previous year, and 9·66, the average of the preceding five years. The highest death-rates were recorded in the districts of Akyab, 21·28, Thayetmyo, 16·55, and Prome, 14·77; while the lowest were registered in Henzada, 7·37, Hanthawaddy (including Rangoon town) 5·80, and Thongwa, 5·75. In the rural areas, the average rate was 11·08, as compared with 7·57 in the towns. Among the latter, the highest fever death-rates were recorded in Kawkareik, 27·12, Pantanaw, 23·55, and Letpadan, 21·39. In Burma, generally, where the total death-rates are not exceptionally high, the recorded death-rates from fever vary inversely with the death-rates from "all other causes."

Dysentery and diarrhœa.

The number of deaths attributed to dysentery and diarrhœa throughout India during 1895 was 242,532, against 262,502 in 1894, but this decrease was confined to the Madras Presidency, to Bengal, the North-Western Provinces and Oudh, and the Punjab; in all the other provinces there was an increase, most marked in the Central

Provinces and Berar. The ratios ranged from ·76 in the Punjab to 8·6 in Berar, and in Madras, Lower Burma, and Ajmere-Merwara were almost identical with the rates recorded in 1894.

As usual, these diseases were most prevalent during the latter half of the year.

The following statement shows the distribution of the deaths from dysentery and diarrhœa in the different provinces, month by month, during 1895 :—

Statement showing the Deaths from Dysentery and Diarrhœa registered in the different Provinces, by months, during the year 1895.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.		Ratio of Deaths per 1,000 of Population.	
													1895.	1894.	1895.	1894.

The number of deaths registered in Bengal in 1895 was 49,871, and the death-rate was ·70 per 1,000 of the population, against ·82 in the previous year, and ·68, the quinquennial mean. The districts in which the mortality was highest were the same as usual, although their relative order was somewhat altered, Calcutta (4·79 per 1,000), Howrah (4·65), Darjeeling (3·90), Balasore (3·21), and Puri (3·20). The lowest death-rates were recorded in Jessore (·04), Purnea (·03), and Rajshahi (·02). The urban mortality (3·52 per 1,000 was, as in past years, enormously greater than the rural (·55). Comparing the records of recent years, it appears that, while the urban mortality tends to increase, the rural mortality tends to decrease slightly. In 1895 the towns in which the highest death-rates were registered were, as last year, Bhadreswar, 11·61 per 1,000, and Serampore 11·48; these were followed by Nasirabad, 8·91, and Hooghly and Chinsura, 8·01. The largest numbers of deaths were registered in December and November, and the least in June.

In the Port of Calcutta, 104 European seamen were admitted to hospital, and four died, equal to a death-rate of 2·79 per 1,000 of strength.

There were 15,523 deaths registered in Assam as due to these causes in 1895, and the death-rate was 3·09 per 1,000, against 2·94, the death-rate of the previous year, and 2·95, the quinquennial mean death-rate. In accordance with the experience of previous years, the highest death-rate, which was 7·79 per 1,000, was registered in Lakhimpur, the next highest rates, 5·12 and 4·58, were registered respectively in Sibsagar and Cachar, while the lowest rates were recorded in Goalpara ·97, and Kamrup ·91. The rural death-rate was 3·01, as compared with 6·75, the average rate in the towns. Among the latter the highest rates were recorded in Golaghat (13·57), Dibrugarh (13·27), Tezpur (10·47) and Dhubri (10·16), and the lowest in Shillong (1·64), and Hailakandi 1·54). The greatest mortality occurred in November, and the least in February.

The total number of deaths ascribed to these causes in the North-Western Provinces and Oudh in 1895 was 42,778 against 66,173 in the previous year, and the death-rate was ·91 per 1,000, as compared with 1·41 in 1894, and 1·07 the quinquennial mean. As usual the highest rates were returned from the hill districts, Garhwal 9·73, Almora 4·83, Dehra Dún 4·88, and Naini Tal 2·10. In the plains the highest district rates were 3·12 per 1,000 in Jhansi, 2·85 in Rae Bareli, and 2·36 in Bareilly, while the

lowest rates were ·09 in Basti, ·08 in Kheri, and ·06 in Bahraich and Mainpuri. The rural death-rate fell from 1·25 in 1894 to ·80, as compared with 2·35 in the towns, where, in 1894, the average rate was 3·62. In Kashipur, in the Tarai, the death-rate was as usual highest, although the 12·84 per 1,000 of 1895 compares favourably with the 15·49 recorded in 1894, and the 19·37 of 1893. Very high rates were registered in Nagina 8·71, Bulandshahr 7·15, Hathras 7·02, Atrauli 7·01, and Moradabad 6·96. The greatest mortality occurred in the months of January and May, and the least in February and March.

There were 15,648 deaths attributed to these causes in the Punjab in 1895, and the death-rate was ·76 per 1,000 of the population, against ·87 in the previous year, and ·83 the quinquennial mean. The highest death-rate was recorded in the Simla district, where the mortality rose from 2·07 in 1894 to 3·26 in 1895, as compared with an average of 1·63 in the previous five years. No explanation of this increase is given. The next highest rate was 1·70, recorded in Umballa, while the lowest rates were ·14 and ·19 registered respectively in the districts of Kohat and Dera Ghazi Khan. The average urban death-rate was 2·33 per 1,000, as compared with ·64 in the rural areas. The town in which the highest rate, 7·60 per 1,000, was registered, was Umballa, followed by Pind Dadan Khan with 5·78, and Karnal with 5·48; in only two towns, Gujranwalla (·97) and Sirsa (·49), were the rates lower than 1 per 1,000. As usual, the mortality was heaviest in September, October, and November.

The number of deaths registered under this heading, in the Central Provinces, was 20,316, and the death-rate per 1,000 of the population, which was 1·78 in 1894, rose to 2·14, as compared with the quinquennial average of 1·81. The districts in which the highest death-rates were recorded were Jubbulpore (4·65), Hoshangabad (4·60), and Narsingpur (4·40); while the lowest rates were registered in Balaghat (·55), Burhanpur (·53), and Bhandara (·30). The average death-rate in towns from these causes was 3·19 per 1,000 against 2·04 in the rural areas. In the former the rates varied enormously; in one small town of 5,000 inhabitants, Mohari, there was no death from dysentery and diarrhœa, while in Damoh (11,753 inhabitants), 227 deaths yielded a death-rate of 19·31 per 1,000. In the other towns the rates varied from 10·57 per 1,000 in Badnur to ·26 in Ramtek. The heaviest mortality was recorded in September (3,282 deaths) and August (3,026), and the lightest in February (788).

The total number of deaths registered as due to these causes in Berar in 1895 was 24,452, and the death-rate was 8·6 per 1,000, as compared with 5·2 in the previous year and 5·4 the mean death-rate of the previous five years. Ellichpur, as usual, headed the districts with a death-rate of 13·8 per 1,000, which has not been surpassed during the last 23 years, the next highest rate was 10·3 registered in Akola; this has been exceeded four times since 1868, namely, in 1874, 1876, 1883, and in 1878, when the mortality from dysentery and diarrhœa in this district reached the enormous rate of 24 per 1,000. By far the lowest rate, 2·8 per 1,000, was recorded in Wun. The average rate in rural areas was 9·0, as compared with 6 per 1,000 in the towns, among which the highest rates recorded were 15·6 in Nandura, 14·0 in Anjangaon, 13·1 in Mehkar, and 13·0 in Ner Pinglai. Contrasting with these high figures were death-rates of ·9 per 1,000 registered in Nandgaon Pett, and ·3 in Mangrul Dastgir. The monthly maxima were attained in August and September, and the minima in January and February.

The total number of deaths registered under this heading in Madras in 1895 was 23,937, and the death-rate, ·7 per 1,000, ·1 per 1,000 less than the quinquennial mean, was practically identical with the rates registered in 1894 and 1893. Excluding the Madras town district, where the rate was 4·9 per 1,000, the highest rates were obtained in the districts of Chingleput (1·9), Malabar (1·6), and South Canara (1·3), while the lowest rates were registered in Anantapur (·3), Kistna (·3), and Kurnool (·2). The urban rate was 2·9, as compared with ·5 in the rural areas, the towns showing the heaviest mortality having been Vizagapatam (10·3), Karur (7·6), and Tuticorin (6·3), places where to foul and damp sites, brackish polluted water supplies are added. In 12 considerable towns, with populations in excess of 10,000, there was no death from dysentery and diarrhœa recorded. The heaviest mortality occurred in August and the least in April.

In both 1893 and 1894 the deaths under this heading, recorded in Coorg, numbered 184, in 1895 the number was almost exactly doubled, and 367 deaths were registered, equal to a death-rate of 2·12 per 1,000, as compared with a quinquennial average of

1·23. In the rural areas the average rate was 1·53 per 1,000, as compared with 8·12 in the municipal towns. The largest number of deaths occurred in June and July, the least in January.

During 1895 the number of deaths from these causes in Bombay was 35,348, yielding a death-rate of 1·88 per 1,000, which is very slightly higher than the rate, 1·84, recorded in the previous year, but decidedly higher than the quinquennial mean of 1·73. The highest district rates were recorded in Sholapur (4·34), Satara (3·88), Belgaum (3·65), and Nasik (3·64), and the lowest in Hyderabad (·12), Thar and Parkar (·06), and Shikarpur (·06). As usual, all the district rates recorded in the Sind and Gujarat Registration Districts were low. The average rate obtained in rural areas was 1·86 per 1,000 against 2·04 in the towns. Among the latter the highest rates were registered in Pandharpur (9·37 per 1,000), Ahmednagar (7·77), Satara (7·50), and Chopda (7·28). The largest number of deaths occurred in the month of August, and the smallest number in February.

Although the number of deaths from dysentery and diarrhœa in Lower Burma, which was 8,794, is the highest on record, it is pointed out that this is an indication of improved registration and not of an unhealthy season. The death-rate from these causes was 1·95 per 1,000 of the population, against 1·92 in the previous year, and 1·21 the average of the previous five years. The highest district rate recorded was 4·40 per 1,000 in Akyab, closely followed by 4·38 in Tavoy. In the other districts the rates of mortality ranged from 3·55 in Bassein to ·44 in Henzada. In the rural areas the average death-rate was 1·87 against 2·46 the average in the towns. In the small towns of Gyobingauk and Donabyu there was no death; among the remaining towns the rates varied, Allanmyo (6·32 per 1,000) and Sandoway (5·14) being at the head of the list, and Zalun (·33) and Shwedaung (·16) at the bottom. By far the largest numbers of deaths were registered in July and August, and the smallest numbers were registered in February, November, and March.

Injuries. In all there were 94,560 deaths from injuries or 1,140 more than in the preceding year. This increase was distributed over seven provinces, but it was in the North-Western Provinces and Oudh that the excess was highest, having numbered no less than 3,123. The ratio of mortality ranged from ·21 per 1,000 in Lower Burma to ·66 in the North-Western Provinces and Oudh and ·76 in Ajmere-Merwara.

All other causes. The number of deaths recorded under "All Other Causes" was 1,282,141 against 1,394,879 in 1894, but in Assam, Berar, Madras, Coorg, and Mysore, the mortality thus classified was higher than in the preceding year.

Vaccination.

The total number of vaccinations performed in 1895–96 among the civil population throughout British India by all the agencies combined was 7,912,086, or 295,226 more than in 1894–95. This increase was confined to primary operations; in re-vaccinations there was a falling off as compared with the preceding year. Out of the total, 7,297,331 were primary operations, of which 6,868,740 proved successful, and 614,758 were re-vaccinations with success in 370,579 cases. In all the provinces, with the exceptions of Madras, the Central Provinces and Berar, the numbers of vaccinations were greater than in the previous year.

As in the two preceding years the average number of operations performed by each vaccinator was highest in the Punjab and lowest in Bengal. In the operations performed by the special establishments the proportion of success in primary cases varied between 98·52 per cent. in Bengal and 87·0 in Madras, and, in re-vaccinations, between 87·98 in Assam and 23·4 in Berar. In the vaccinations performed in dispensaries the percentage of success in primary cases was highest in Bengal (95·40), and lowest in the North-Western Provinces and Oudh (75·48) and Coorg (61·73); and in re-vaccinations it ranged from 82·26 in Assam to 37·78 in Lower Burma and 28·0 in Coorg.

Except in the Central Provinces and Upper Burma the numbers of infants protected by vaccination were, in every province, greater than in 1894–95. The total number of children under one year of age who were successfully vaccinated was 2,751,764, and of those between one and six years of age 3,372,925, the corresponding figures for the preceding years having been, respectively, 2,692,885 and 3,200,454. As noted in the report for 1894–95, the state of infant vaccination is still backward in Bengal, Assam, Madras, Coorg and Burma. The ratio of successful vaccinations per 1,000

of population was greater than in 1894–95 in every province, excepting the Punjab, Central Provinces, Berar and Madras.

The following comparative statement shows the main features of the working of the Vaccination Department during the years 1894–95 and 1895–96.

Comparative Statement of Vaccination in the different Provinces of India, excluding Ajmere-Merwara, in 1894–95 *and* 1895–96, *together with the death-rates from small-pox during* 1894 *and* 1895.

Province.		Population.	Number of Vaccinations performed.			Percentage of Successful Cases.		Persons successfully vaccinated per 1,000 of population. * Refers to Special Vaccination Establishment only.
† Calculated on figures taken from Sanitary Reports excluding Upper Burma.

During the year 1895–96 the supervising staff in Bengal consisted of three Deputy Sanitary Commissioners, 48 Civil Surgeons, 211 Native Superintendents and 13 Head Vaccinators, and the Vaccinating Staff, of 157 operators paid by Government, 67 paid by district boards, 281 attached to municipalities, dispensaries, etc., and 3,156 licensed men, who are not paid from public funds, but are allowed to make a small charge for each operation, their work being controlled by the Department. The total number of operations performed throughout the Province increased from 2,174,097 in 1894–95 to 2,277,081, of which 2,179,900 were successful cases of primary vaccinations and 20,572 successful re-vaccinations. In primary operations the percentage of success reported was 98·39; this, though slightly lower than in the preceding year, is still incredibly high, and is attributed mainly to the exclusion of failures from the returns, but, in a measure also, to classifying as successful, not only in cases in which success had been only partial, but even absolute failures. In this connection, the provincial Sanitary Commissioner having pointed out that in Bengal only two punctures in each arm are made, whereas in the Punjab the three punctures in each arm give a better chance of success, and that no information regarding the numbers of good cicatrices obtained in each case is furnished, the Lieutenant-Governor has accepted the suggestion that, in future, three punctures shall be made in each arm, and that the returns shall show exactly how many points in each case of vaccination have succeeded. The percentage of success in re-vaccination was 50·04 against 36·83 in the previous

year, and 51·26 in 1893–94. Instancing the remarkable disappearance of small-pox from Prussia, Dr. Dyson urges on Government and local bodies the importance of providing that every boy entering school and the public service should be vaccinated or re-vaccinated.

In recent years a distinct advance has been made in the protection of infants. In 1892–93 the percentage of the estimated number of infants born who were vaccinated successfully was 11·4, in 1893–94 it was 12·9, in 1894–95 the percentage rose to 14·2, and during last year to 14·7.

Of the different agencies the vaccinators employed by the district boards displayed the greatest energy, the average number of operations performed by each man having been 881, while the municipal vaccinators did least work, their average having been only 424 per man.

The number of operations verified by the Deputy Sanitary Commissioners was only ·86 of the whole, but it must be remembered that these officers have to carry on their inspections in the most inaccessible parts of the province. Civil Surgeons verified 8·8 per cent. of the numbers vaccinated; five officers inspected over 10,000 cases each, among them, Surgeon-Major Peck, who inspected 13,997 cases, and Surgeon-Lieutenant-Colonel Russell, who inspected 13,487. The proportion verified by District Inspectors was 32·77 per cent., and by the Sub-Inspectors 62·52; the quantities of work done by these subordinate officers were very unequal.

Vaccination was carried on with humanized lymph, with fresh calf lymph, and with calf lymph mixed with lanoline, but no comparison of the relative value of these is possible, as the "erroneous practice of excluding unsuccessful operations and including "repetitions in the arm-to-arm method is still in vogue." Dr. Dyson advances strong reasons for the exclusive use of calf lymph. The general advantages of this method are, of course, well known, but the difficulty in obtaining infants as vaccinifers, and the practical certainty that those obtained are the children of poor low-caste parents, are among the disadvantages peculiar to India of the arm-to-arm method.

The most notable event in the year was the success attending the efforts to introduce vaccination among the Ferazis of Eastern Bengal. The Ferazis are a strait sect of Suni Muhammadans. Among their religious tenets is the prohibition of vaccination, on the grounds that prophylactic measures should not be taken against disease, and that it is a sin for a Mussulman to have pus or blood injected into his body; and, among their superstitions, the belief that Government has instituted the practice of vaccination in order to detect and capure a future ruler, now living among them, in whose veins milk flows, and not blood! Hitherto the Ferazis have resisted vaccination in the most determined manner, and their communities have suffered much from smallpox. By patient endeavour, beginning with the high priest, Dr. Deare succeeded in inducing no less than 36,240 of the sect to allow themselves to be vaccinated with lanoline-lymph. The introduction of vaccination among the Ferazis in other districts has followed the successful efforts made in Faridpur.

While the number of vaccinators employed in Assam during 1895–96 was slightly less than in the preceding year, the number of operations performed by them rose from 181,477 to 233,812, the average number performed by each man having risen from 789 to 1,025. Of these 227,114 were primary vaccinations, and 6,698 cases of re-vaccination, and the percentages of success were 97·74 and 87·98 respectively, as compared with 87·80 and 61·25 in 1894–95. The high rate of success reported in primary vaccinations is attributed to the improvement in the lymph supplied from the depôt at Shillong, but the results are considered by the Chief Commissioner to be suspiciously good; he doubts the accuracy of the figures, and is inclined to believe that unsuccessful operations are excluded from the lists in parts of the province. No explanation of the very high percentages of success in re-vaccination attained in all the districts is given. The number of operations performed by medical officers and subordinates attached to the dispensaries fell from 12,302 in 1894–95 to 10,456 in 1895–96. Of these 10,005 were primary vaccinations and 451 re-vaccinations, and 95·08 and 82·26 per cent. respectively were successful. Besides these operations, 16,422 primary operations, upwards of 10,000 more than in 1894–95 were performed by private agencies on tea estates, and 86·74 per cent. were successful.

There were 47,176 infants under one year of age protected against 40,082 in the preceding year, and 37,112 in 1893–94.

Inoculation is still practised in parts of the Surma Valley and in the Lakhimpur district. In May 1895 two persons were charged in the Court of the Deputy Commissioner of Cachar, the one for causing death by a rash and negligent act, in that he inoculated a child with small-pox from which it died, and the other for doing

a negligent act likely to spread infection of a disease dangerous to life, in having inoculated certain children, one of whom contracted small-pox and lost his eye-sight. They were each sentenced to a week's imprisonment and a fine of 20 rupees. On appeal the Sessions Judge remitted the sentence of imprisonment, but the fines were allowed to stand.

The bovine lympth depôt at Shillong was worked satisfactorily during the year, and there was no complaint made of the quality of the lymph supplied. In view however, of the supply proving insufficient, orders have been issued for the use of fresh calf lympth at each district head-quarters. It was found in the depôt that lanoline-lymph paste of a strength of 1 in 6 gave better results, and was more certain, than the methods previously in use, and it was also observed that punctures produced better vesicles on the calf than scarification.

The average number of vaccinators employed in the North-Western Provinces and Oudh in 1895–96 was 854, against 828 in the previous year, and the number of operations performed by each man rose from an average of 1,718 to 1,754. The number of operations performed was 1,497,899, of which 1,436,591 were primary and 61,308 re-vaccinations, the percentages of success having been 94·87 in the former and 66·02 in the latter, as compared with 93·68 and 63·22, in 1894–95. Besides these, the medical subordinates attached to dispensaries performed 1,199 primary operations, of which 75·48 per cent. were successful, and 155 re-revaccinations, of which 41·93 per cent. succeeded. The number of infants protected during the year rose from 562,481 in 1894–95 to 570,227, or 30·2 per cent. of the estimated births of the year.

Although the Vaccination Act is in force in all the municipalities, it is not worked so efficiently as it ought to be. The vaccination register, which should be kept up by the municipal authorities, is practically the same as the birth register; but the birth registers are generally defective, so that children escape being vaccinated, while the work of keeping up the vaccination register is frequently performed by the vaccinators themselves. The number of operations verified by the Deputy Sanitary Commissioners and Civil Surgeons was 145,086 or 9·68 per cent. of the total, and the number verified by the Assistant Superintendents of Vaccination and other inspecting officers was 446,827, or 29·83 per cent. of the whole. The percentage of cases found to be successful by the former was 95·10, and by the latter 94·18, while the success claimed by the vaccinators was at the rate of 93·77 per cent. only. With the exception of the depôt at Lucknow, none of the lymph depôts in the province seem to have been worked altogether satisfactorily. A scheme is being considered for the extension of the operations of the Lucknow depôt during the cold season, and for the establishment of a similar depôt in the hills, whence lymph can be obtained by such persons as require it during the recess season, and from which supplies for the commencement of operations throughout the province, in September, can be sent.

Small-pox broke out in epidemic form in the autumn of 1895, and was most severe in the south-eastern and southern districts. Very soon it was noticed that large numbers of adults, who had been vaccinated, suffered from the disease, although in a slight and modified form, and special efforts were made to extend re-vaccination, with the result that the number of successful re-vaccinations rose from 16,203 in the preceding year to 36,318.

The supervising staff in the Punjab remained numerically the same as in 1894–95, viz., one Deputy Sanitary Commissioner, six Divisional Inspectors, and 34 Native Supervisors, but the average number of vaccinators employed, including 21 belonging to the special staff, and six employed in cantonments, was 300 in 1895–96, or four fewer than in the previous year. During the year a new system was introduced to secure more systematic working of the operators, greater thoroughness in the work, and more reliable statistics regarding it. Under this system the vaccinators began their work in bodies, each under the control of a supervisor, who is responsible for the quantity and quality of the work. The agency is under the general supervision of the Civil Surgeon, who is to see that his district is thoroughly traversed. At first the new plan, being unpopular with the vaccinators, who were formerly able to do pretty much as they pleased, was not very successful and the number of operations fell off, but, as the result of warnings, work was undertaken energetically, and the deficiencies were more than made up.

The total number of primary operations performed by the district staff was 624,896, as compared with 592,992 in 1894–95, and the number of re-vaccinations 204,832, against 224,354 in the previous year. The falling off in the number of the latter was due to the effect of orders issued regarding the practice of indiscriminate

re-vaccination. The percentages of success obtained were, in primary cases 93·36, and in re-vaccinations 56·66. There were 61,708 primary operations and 17,597 re-vaccinations performed by the special staff, with success at the rates, respectively, of 90·29 and 51·22 per cent. The cantonment staff performed 4,858 primary operations and 6,015 re-vaccinations, of which 94·77 and 75·58 per cent. were respectfully successful. Besides these, the dispensary establishments performed 2,282 primary operations, and 987 re-vaccinations, of which 93·38 and 51·57 per cent. respectively succeeded. The number of infants successfully vaccinated was 487,217, or 14,910 more than in the previous year, but, notwithstanding this increase, nearly one-half of the number of children born during the year remained unprotected.

Out of the 923,175 operations performed in the province, 657,773, or 71 per cent., were inspected by officers of the Department. Among the Civil Surgeons, some of whom did a great deal of verification, the Civil Surgeon of Ferozepore inspected the enormous number of 19,664 cases. Dr. Roe praises highly the work done by the six divisional inspectors and strongly recommends the appointment of such officers in every division of the province.

Of the large Native States, Patiala heads the list with 98,845 operations, of which 93·45 per cent. of the primary vaccinations, and 40·50 per cent. of the re-vaccinations were successful. In Kurram 2,995 primary operations and 42 re-vaccinations were performed, of which, respectively, 98·63 and 47·62 succeeded.

During the year 93 per cent. of the operations were performed with buffalo-calf lymph, but the difficulty in procuring calves, instead of diminishing, has, it is said, become greater from year to year. Of special importance, therefore, are the experiments in the preservation of lymph, which have been carried on by Surgeon-Major Bamber. White vaseline was the material used, and a lymph-paste made with this substance, was tested under identical conditions, with the same lymph preserved in glycerine and lanoline. The glycerine preparation was found mouldy after being kept a fortnight, and the results obtained with the vaseline paste were better than those obtained either with lanoline paste prepared in Multan or with a specimen of lanoline-paste received from Mysore. Surgeon-Captain James, the Deputy Sanitary Commissioner, who assisted Surgeon-Major Bamber in his later experiments, thus sums up the advantages of vaseline paste :—

"From what I have seen I have come to the conclusion that vaseline lymph has the following advantages over the fresh lymph :—

"(1.) It can be easily carried about in the pocket or sent by post. This does away with the necessity of carrying a child or a buffalo calf as a vaccinifer to the place where the vaccinations are going to be performed.

"(2.) Fresh lymph can only be used on the day the vesicles are ripening, and all lymph not used on that day is wasted, vaseline lymph keeps good for several months and can be used whenever required.

"(3.) Vaseline lymph, being diluted with five times its weight of vaseline, five times as many people can be vaccinated from the same calf as would otherwise supply the fresh lymph.

"(4.) If the vaseline be all manufactured at a central depôt, the vaccinators would be saved all the trouble and time wasted in procuring and vaccinating a buffalo calf at every village or town in which they work. The Special Staff Vaccinator using buffalo calves can usually only vaccinate about 500 people a month. Dr. Bamber's vaccinators using vaseline lymph were able to vaccinate 2,000 people a month. This shows the saving of time which the new lymph ensures.

"I think it superior to lymph stored in capillary tubes, because :—

"(1.) It is more certain in its results, and keeps longer.

"(2.) Much larger quantities can be sent out for immediate use.

"(3.) Capillary tubes are very fragile, and are much more readily broken in transit, specially if sent by post.

"(4.) Pure lymph often coagulates in the tubes, vaseline lymph never does.

"Vaseline lymph seems to be better than lanoline lymph, because—

"(1.) It is of more fluid consistence and less tenacious than lanoline and, therefore, is much easier to work with.

"(2.) It is a mineral substance, and not an animal product as lanoline, and is, therefore, much more acceptable to Hindus.

"(3.) Being clear it is easy to see whether it has properly mixed with vesicles or not. Lanoline is opaque, and it is impossible to determine whether it contains vesicle, &c., or not. This is an important matter if the preparation is left to natives.

"(4.) Moulds, &c., will not grow on vaseline, but they do so on lanoline.

"(5.) So far we have found that vaseline gives better results than lanoline.

"The only disadvantage which I know of against all these advantages is that the new vaccine requires much more careful preparation than the older kinds."

On account of certain rumours to the effect that children who had been recently vaccinated had contracted small-pox, and because one experienced Civil Surgeon had expressed the belief that buffallo-calf lymph was not protective, Dr. James was induced to specially inquire into the prophylactic value of this lymph. His investigations are of peculiar interest, as special inquiry into the degree of prophylactic power of buffalo-calf lymph has not previously been made, and as it is known to die out sooner than that of the lymph propagated through cow-calves. Dr. James could find only one mild case, where a child, who had been vaccinated more than six days previously, had contracted small-pox, and this case was one of bad vaccination, for only two minute marks, said to be vaccination scars, could be detected.

Regarding the efficacy of the buffalo-lymyh Dr. James writes:—

"I visited 23 houses where there was small-pox present and noted what other children were living in the same buildings, and whether or not they had been vaccinated. I found 78 children altogether, of whom 40 had, at some time or other been vaccinated, only two got small-pox, of the remaining 38, who had not been vaccinated, 28 got the disease and only 10 escaped. In one house one child out of six had not been vaccinated. It got the disease and the rest escaped. In another house one out of five children had not been vaccinated and was the only one who contracted the disease. In a third house, that of a Khatri Sikh, none out of five children had been vaccinated. They all got small-pox."

The strength of the Central Provinces establishment was the same as in 1894–95, viz., 27 Native Superintendents, including two in the Feudatory States, and 257 Vaccinators, including 48 in the Feudatory States. The total number of operations performed in 1895–96 was 449,720 against 470,592 in the previous year, the falling off having been in the numbers performed in British territory, for in the Feudatory States there was an increase of 7,569 operations. The percentage of success obtained in primary operations, of which there were 383,556, was 96·37 per cent., and in 66,164 re-vaccinations, 82·11. In addition to these there were 15,755 operations performed by the dispensary establishments against 18,673 in 1894–95. Of these 13,705 were primary operations, and 2,050 re-vaccinations, and success was obtained at the rates of 92·08 and 77·6 per cent. respectively. The decrease in the amount of work done is said to have been due in part to the prevalence of scarcity and distress, and in part to the negligence of the vaccination establishment. The total number of infants protected was 239,865, or 49·3 per cent. of the estimated births of the year. Civil Surgeons inspected 18·58 per cent. and Native Superintendents 51·13 per cent. of the total number of vaccinations, and found, respectively, 87·62 and 91·01 per cent. of operations successful. The lymph used was prepared by Civil Surgeons at each head-quarter station, instead of, as in former years, in one central depôt at Pachmarhi. A supply of calf lymph sent out from England was distributed, but, except in one case, proved inert. In all, 10,199 calves were vaccinated, and the operation was successful in 9,183 cases. With the lymph obtained from them, 283,759 vaccinations were performed, and 264,834 were successful.

The vaccination establishment in Berar consisted of seven Native Superintendents, 45 vaccinators, six apprentices, and seven peons. The total number of operations fell from 137,152 in 1893–94, and 114,639 in 1894–5, to 106,605, the decrease being due to the unhealthiness of the last two seasons, resulting in sickness and mortality among the children and the occasional illness of members of the vaccinating staff. For the same reasons, the number of operations performed by each vaccinator fell from averages of 3,117 and 2,605 in the two preceding years, to 2,423 per man in 1895–96. Of the total number of operations performed, 92,694 were primary and 13,911 re-vaccinations, and the percentages of success were, respectively, 95·9 and 23·4, against 94·7 and 23·1 in 1894–95. The number of infants under one year of age, who were protected, was 67,439, or 58·2 per cent. of the estimated births of the year. Of the total number of operations, 1·8 per cent. were inspected by the Sanitary Commissioner, who found 97·1 per cent. to be successful, and 52·0 by Native Superintendents, who reported 94·7 successful.

The Vaccination Act is now in force in all the municipalities of the province except Karanja, and it has, so far, worked satisfactorily. No prosecutions have been found necessary, the mere serving of the prescribed notice having been sufficient to induce parents who were backward to bring forward their children.

Since 1890 vaccination has been carried on with lymph taken direct from the calf, the season's work, being started with lanoline paste prepared at head-quarters, under the direct supervision of the provincial Sanitary Commissioner.

During 1895–96, the supervising staff in Madras Presidency consisted, as in the previous year, of one Deputy Sanitary Commissioner and 58 Native Inspectors. The

134528

average number of vaccinators employed rose from 806 in 1894–95 to 842, and the number of operations performed by them, from 1,172,512 to 1,178,970. The increase was not, however, proportionate to the increase in establishment, for the number of operations performed by each man fell from an average of 1,455 in 1894–95 to 1,383. Of the total number of operations performed, 1,103,099 were primary and 75,871 re-vaccinations, and the ratios of success were, respectively, 87 and 80·5 per cent. In addition to these, 19,201 operations, or 7,209 less than last year were performed by the establishment attached to dispensaries. Of these, 17,526 were primary vaccinations, of which 89·0 per cent. were successful, and 1,675 were re-vaccinations, of which 71·0 per cent. succeeded.

In the Presidency as a whole, 22 per cent. of the number of children whose births were registered during the year, were protected, but the percentages varied greatly in the different districts, the extremes having been Madura, where 65·6 were protected, and Malabar where the percentage was only 1·9. In only two of the municipal towns, Kumbakonum (49·2) and Srivilliputtur (18·4), did the percentage of children born during the year and who were successfully vaccinated fall below 50. Of the total number vaccinated, 2·3 per cent. were inspected by Civil Surgeons, and 49·5 by Native Inspectors, and the percentages of cases found to be successful by these two classes of officers, were 90·6 and 89·7 respectively.

Vaccination was carried on with lymph taken direct from the calf, with bovine lymph preserved in tubes and with similar lymph mixed with glycerine and with lanoline. The following statement shows the extent to which these varieties were used and the degree of success obtained with each —

"Vaccinations direct from the calf, 300,518 with 97·8 per cent. success.
" with calf lymph preserved in tubes, 98,703 with 95·1 per cent. success.
" " mixed with glycerine, 641,181 with 89·5 per cent. success.
" " mixed with lanoline, 23,193 with 94·5 per cent. success.

In Coorg the staff acting under the orders of the Civil Surgeon consisted of one Native Inspector and nine vaccinators. The average number of operations performed by each vaccinator rose from 868 in 1894–95, to 1,157 in 1895–96, and the number of vaccinations from 7,815 to 10,411. Of the total, 8,721 were primary operations, and 1,690 re-vaccinations, of which 95·72 and 86·27 per cent respectively, succeeded. Beside these, 602 vaccinations were performed at the dispensaries, of which 61·73 per cent. of the 452 primary operations were successful, and 28·0 of the 150 re-vaccinations. The Civil Surgeon inspected 4·71 per cent. of the operations and the Native Superintendent 32·59; the percentages of success found by these officers were 91·71 and 99·47 respectively.

The percentage of children protected was 17·2 against 9·3 in the previous year.

As usual, all the operations were performed with calf lymph.

In the Bombay Presidency, including certain Native States, the vaccination establishment consisted of five Deputy Sanitary Commissioners, two Superintendents of Vaccination, 45 Inspectors of Sanitation and Vaccination, 16 clerks and 468 vaccinators, besides 511 peons and *karkuns*. The total number of operations performed during the year was 803,850, or 35,621 more than in 1894–95; the average number performed by each vaccinator was 1,854, against 1,779 in 1894–95. Of the total, 727,935 were primary operations, of which 93·25 per cent. were successful, 74,672 re-vaccinations, of which 57·59 per cent. were successful, and 1,243 were repetitions, in cases where the first vaccination had failed. In addition to these, 951 primary operations and 523 re-vaccinations were performed by dispensary establishments. The number of infants successfully vaccinated was 526,324, or about 58 per cent. of the estimated number of births, against 520,074 in the previous year. Of the 669,149 persons vaccinated in British territory, 7·03 per cent of the operations were inspected by Deputy Sanitary Commissioners and 37·67 per cent. by Native Inspectors and Superintendents; the former officers found 95·55 per cent. to be successful and the latter 99·01 per cent.

The use of bovine lymph is being gradually extended. It was exclusively used in the city of Bombay, and it was used in Poona, Sholapur, Ahmednagar and Karachi, and in selected towns and rural tracts in the Western, Central and Southern Registration Districts.

In the Native States of Baroda, Cutch, Kathiawar, Palanpur and Idar, the statistics of which are now compiled separately from those of the Presidency, 213,099 primary operations were successful at the rate of 95·53 per cent., and 5,255 re-vaccinations at the rate of 70·88 per cent. In these States, 162,069 infants were protected, or 4,904 more than in the previous year.

In Lower Burma the vaccination staff consisted of 20 Superintendents of Circles, one Deputy Superintendent (Rangoon), nine Native Superintendents and 123 vaccinators. The number of operations performed rose from 206,092 in 1894–95 to 242,845, but the average number performed by each vaccinator fell from 2,677 in that year to 1,974 in 1895–96. Of the 215,468 primary vaccinations, 91·21 per cent. were successful, and of the 27,377 re-vaccinations 46·01 per cent. succeeded. By establishments attached to dispensaries 1,291 primary vaccinations, of which 92·02 per cent. were successful, and 929 re-vaccinations, of which 37·78 were successful, were performed. There were 41,107 infants protected or about 22 per cent. of the estimated number ef children born during the year.

Civil Surgeons inspected 14·61 per cent. of the cases, and other inspecting officers, 18·13.

In the Upper Province, the staff consisted of 19 Superintendents of circles, one Deputy Superintendent (Mandalay) and an average of 54 vaccinators. The number of operations rose from 114,863 in 1894–95 to 115,703, but the number of operations performed by each vaccinator fell from 2,393 to 2,143. Of the total, 113,778 were primary operations, of which 92·67 per cent. succeeded, and 1,925 were re-vaccinations, of which 66·65 per cent. were successful. Besides these, dispensary establishments performed 4,765 primary operations and 210 re-vaccinations with the rates of success of 91·46 and 77·62 per cent. respectively. There were 30,741 infants protected. Civil Surgeons inspected 33·49 per cent. of the operations, and Native Superintendents and others 12·39 per cent.

For some years past, vaccination has been carried on in the Shan States, but, hitherto progress has been limited. In the Northern States in 1894-95, 941 persons were vaccinated, but the operation succeeded in only 73 per cent. of the cases. In the Southern States there were 3,169 successful cases or about 92 per cent. of the total operations.

The establishment consisted, as in 1894–95, of two Superintendents and 12 vaccinators, but the number of operations rose from 13,356 to 15,978, and the average number performed by each vaccinator from 1,113 to 1,331. The primary operations numbered 15,583, of which 96·24 per cent. proved successful, and the re-vaccinations 395, of which 87·09 per cent. succeeded. The number of infants protected rose from 8,782 in 1894–95 to 10,056 in 1895–96.

Civil Sanitary Works.

In comparing last year's income and expenditure of the municipalities in Bengal with former years, a difference of arrangement must be noted. Formerly the figures dealt with the calendar year; but, as confusion has arisen when comparisons were made with similar information furnished in other reports dealing with municipal administration, in which reference is made to the official year, the local Sanitary Commissioner, on whose report the following account is based, has made use of the figures relating to the official year, ending March 31st.

Excluding Calcutta, there are 146 municipal towns in Bengal. The total income of these, which, in 1893–94, including a balance carried on from the previous year, was Rs. 37,32,074, rose, in 1894–95, including a balance from 1893–94, to Rs. 45,53,651. Of this amount 51·49 per cent. was spent on original or recurring sanitary works, 11·37 per cent. on roads, and the balance on other requirements.

Omitting expenditure which was met from capital, the following amounts were spent on sanitation:—On conservancy Rs. 8,79,988, on water-supply Rs. 7,97,609, and on drainage Rs. 2,73,741. The average proportion of municipal income devoted to original sanitary works was 5·97 per cent., and to sanitary works of an annually recurring nature 35·36 per cent. The towns in which the largest percentages of income were spent on original works were, Jagadispur, 29·25, Cossipore-Chitpur, 21·61, Purulia, 21·20, Baruipur, 21·04, and Jessore, 20·74; on the other hand, in 27 municipalities, there was no expenditure on original works. The town in which the largest percentage of income was expended on ordinary sanitation, was English Bazar, in Malda, 61·65, and the town in which the least was thus spent was Joynagore, 3·48.

During the year the Howrah water-supply works were opened, an additional Rs. 5,13,432 having been spent on them.

A further sum of Rs. 1,00,000 was devoted to the Arrah water-supply. The pumping station is situated at Bahiara, a village on the bank of the Sone, about $5\frac{1}{2}$ miles from Arrah. The Sone water is remarkably pure; it is filtered at the pumping station and forced, through a 13″ main, 28,400 feet long, to an elevated

reservoir in Arrah, whence it gravitates through the distribution pipes. The average quantity of water consumed each day was 150,000 gallons.

The Cossipore-Chitpur water-supply scheme and the drainage schemes for Patna and Muzaffarpur were completed. In other towns, and in the districts, a large number of useful improvements were carried out during the year by municipal authorities, district and local boards, and private individuals. The total amount contributed by private individuals was Rs. 1,88,875, as compared with Rs. 1,51,453 in 1893–94.

Regarding rural sanitation, Dr. Dyson entertains somewhat pessimistic views; the utmost that has been accomplished by the persuasive efforts of the local officers of the Government, has been to convince some village headmen that their village sites should be kept clean and the sources of water-supply uncontaminated; none have been persuaded to take steps to enforce these requirements. Local self-government union committees have, however, been established in selected areas with the view of carrying out measures for the improvement of village sanitation.

The Sanitary Board met seven times; the principal subjects of discussion at these meetings were the following:—

(1.) The improvement of the water-supply of Darjeeling by the construction of settling-tanks.
(2.) A scheme for the supply of drinking water to the town of Gaya.
(3.) The drainage and sewerage of Howrah.
(4.) The chemical and bacteriological examination of water-supplies, and the necessary additional establishment required by the chemical examiner to carry these out.
(5.) The drainage of the town of Krishnagar by the excavation of the Anjona Khal.
(6.) A water-supply scheme for Berhampore.

Preliminary estimates were prepared under the orders of the Board for:—

(1.) A sewerage scheme, including a supply of unfiltered water for flushing purposes for the town of Dacca, to cost Rs. 13,50,000;
(2.) two schemes for the surface drainage of Hooghly, to cost Rs. 54,000 and Rs. 70,000, respectively.

The scheme for the supply of filtered water to Berhampore is at present in abeyance. The Maharani Surnamoyee, C.I., had generously undertaken to defray the cost, estimated at Rs. 2,21,000, of a scheme to bring water from the Bhagirathi. The Board found that the water of the Bhagirathi is of very bad quality, and suggested the sinking of wells in one of the old river-beds, but the Municipal Commissioners refused to accept this suggestion. The difficulty has, however, been overcome, and there is every prospect of the work being commenced within the next three months. Orders have also been received from the Lieutenant-Governor to send up for administrative sanction the scheme for the supply of filtered water to Midnapore.

A detailed estimate for the extension of the Bhagalpur water-works at a cost of Rs. 3,14,000 was prepared. This has been sanctioned by Government, and work will be commenced as soon as possible.

The following projects were considered:—

(1.) An estimate for a small filtered water-supply for Faridpur; this was not approved, as there were grave defects in the filters proposed. The municipality were advised, and agreed, to get the design worked out by the Sanitary Engineer.
(2.) An estimate for the supply of filtered water to Pabna was returned to the municipality for revision.
(3.) An estimate for the installation of Pasteur-Chamber and filters in the Darjeeling water-supply. The Board did not recommend the introduction of these filters, because sufficient trial had not been given to the new settling-tanks, and because sand-filtration continued to be used for all large water-supplies as the most efficient and least expensive method. The views of the Board were, however, not concurred in by Government, as the terms offered by the contractors were so favourable, that, even if the experiment proved a failure, the municipality could not lose, and the estimate has been sanctioned.
(4.) An estimate for improving the drainage of Krishnagar, by the excavation of the Anjona *khal*: the Sanitary Engineer is to work out the details.
(5.) Estimates for the extension of the Bhagalpur waterworks and for the sewering of Dacca, of which mention has already been made.

A large number of miscellaneous references were made to the Board, among them an inquiry by the Chairman of the Serampore Municipality as to the cost of providing

filtered water to that town from the pipes which run through it for the supply of Howrah. The Chairman was informed that it was for the Municipal Commissioners of Howrah to decide whether they could spare any water, and this is unlikely, as the cost of the Howrah scheme was made as low as possible.

In April the Engineer to the Board was permitted to visit the Punjab to examine the system of water-supply from wells used there. Many of the water-supply works in Bengal were inspected by him during the year.

Excluding the towns of Sunamganj, Karimganj, and Maulvi Bazar, in which allowances for sanitary purposes are made by the Local Boards, the aggregate income of the municipalities, stations, unions, and towns in Assam was Rs. 2,60,994, and a sum of Rs. 1,66,675, or 63·86 per cent., was devoted to sanitary purposes. Of this total, however, Rs. 51,500 were spent on roads and bridges, and if this is deducted, 44·13 per cent. was spent on sanitation proper. The details of expenditure were, Rs. 37,859 on water-supply, Rs. 62,506 on conservancy, Rs. 9,227 on drainage, and Rs. 16,304 on markets, village sites, and various sanitary improvements.

Considerable attention was paid to the improvement of the urban water-supplies, and in this respect Gauhati is in advance of the other towns. A comparatively large sum was spent by that municipality in rendering the filtering beds efficient, and, when the arrangements for pumping water from the river are completed, the townspeople will be provided with a sufficient supply of pure water. A new engine has been ordered, and when it arrives, water will be pumped direct from the river into the settling-tanks; the old engines will afterwards be repaired and kept in reserve. In some of the other towns, new masonry wells were constructed, pumps have been provided and reservoirs with taps, so that persons drawing water cannot contaminate the water in the wells. Every effort is made to encourage the smaller towns to improve their water supplies; sanction is refused to the expenditure of large sums of money on the construction of new tanks, and it is hoped that the existing tanks, from which drinking water is taken in the various towns, will soon be fenced in, and the water raised into small reservoirs, from which it can be drawn off.

The small sum spent on drainage is accounted for by the fact that the areas included within municipal limits are so large that effective drainage schemes were considered impossible. All that was done, in most towns, was to clean the open ditches. In Gauhati, however, the drainage of the *bazar* has been taken in hand, a complete scheme has been prepared, and, in accordance with it, masonry side-drains are being laid in the streets. The arrangements for the removal of excreta have been improved in the cases of several towns, and trenching has been more carefully supervised than formerly. The local administration has brought to the notice of the Municipal Committees the necessity for constructing incinerators in those places in which the water-logged state of the soil during the rainy season renders efficient trenching impossible.

The members of the Sanitary Board met twice during the year. They were chiefly occupied with the preparation of rules for the sanitation of villages. A draft Village Sanitation Regulation, adapted to the requirements of Assam, from the North-Western Provinces and Oudh Village Sanitation Act, II. of 1895, was prepared and referred to the local administration for such further action as might be thought necessary.

The income of the 103 municipalities in the North-Western Provinces and Oudh, excluding opening balances, aggregated Rs. 55,06,002. The expenditure on water-supply was Rs. 8,29,523, on conservancy Rs. 8,97,945, on drainage Rs. 3,42,500, and, on markets and slaughter-houses, Rs. 56,432.

Steady progress continued to be made in the sanitation of most of the larger towns, and, although the lack of skilled local supervision is serious, expenditure is gradually being directed on more scientific lines, and less money is spent on well-intentioned but mis-directed efforts than in past times. The villages, however, still remain much as they were. The Village Sanitation Act has been applied to 34 villages and small towns, but until organised action is taken upon it, improvement cannot be expected.

The following notes refer to sanitary works of importance which are in course of development and construction:—

(1.) The Cawnpore waterworks were opened on the 17th March 1894, and, during that year, five gallons of water per head of the population were supplied daily. During 1895, a total of 429,689,695 gallons were supplied, equal to 8·41 gallons per head. Forty-five new house-connexions were made. Analyses of the water supplied were always satisfactory.

(2.) The Lucknow waterworks were opened on the 21st July 1894, and during that year, 65,809,757 gallons of water were pumped into the distribution mains. In 1895, the total quantity of water supplied was 252,701,609 gallons, or 2·6 gallons per head of the population. No new house-connexions were made during the year, and only three applications for the extension of pipe lines in the city were received. The water was invariably reported by the analyst as fit for drinking.

(3.) At Meerut, the foundation stone of the new waterworks was laid by the Lieutenant-Governor early in August, and good progress has been made with the work.

(4.) At Agra, where 6·9 gallons of water per head of the population were supplied from the works in 1894, the average consumption rose to 8 gallons a head, or 441,872,276 gallons. Fifty-eight new house-connexions were made during the year, bringing up the total to 563. Analyses showed the supply of water to be good.

(5.) At Allahabad, 479,469,932 gallons of water were supplied, and the daily consumption rose from 7 to 8 gallons a head. The number of new house-connexions was 262, and the total is now 1,251. The quality of the water was reported to be excellent.

(6.) At Benares, the consumption of water from the supply works rose from 5·9 gallons per head in 1894 to 7·5 gallons, equal to a total of 573,545,691 gallons, in 1895. New house-connexions, to the number of 628, were made, bringing the total to 3,005. The water was invariably reported to be good.

(7.) At Agra, fair progress has been made with portions of the drainage and paving schemes. Plans and estimates for the construction of an intercepting sewer along the river bank, and for draining and paving Nyee Basti, have been submitted to the Sanitary Board.

(8.) At Benares, 76 per cent. of the work on the main sewer had been completed at the end of the year, but the work of construction of the main sewer and of the branches has been delayed by the difficulty experienced in obtaining burnt bricks and pipes up to specification.

(9.) At Cawnpore, the sewerage and drainage works in the *Sadr Bazar* were practically completed on the original estimate.

(10.) At Hardwar, the construction of a trial incinerator of the Garlick type was begun.

There were four meetings of the Sanitary Board at Naini Tal during the hot season. The following subjects were among those discussed:—

(1.) The question of closing all public and private burial grounds within municipal limits. The opinion was recorded, that, so far as possible, burials should not be permitted except in places approved by the Magistrate and the Civil Surgeon as local Health Officer.

(2.) The Government order calling for a report on the best method of maintaining village sanitary records. The Sanitary Commissioner was asked to inquire into procedure adopted in the Central Provinces, and to prepare a note on the subject for the opinion of the Board. This note was discussed at the second meeting, when it was resolved that the secretary should draft a letter in reply to Government.

(3.) The more pressing drainage works required in the Meerut and Agra divisions. It was resolved that the Irrigation Department should prepare a list for submission to Government.

(4.) The complete sanitation of places of pilgrimage. The levying of a small pilgrim tax, such as is already imposed at Hardwar and Benares, was suggested.

(5.) The supply of pure water to the pilgrims at the *Magh Mela* at Allahabad. The Board recognised that it would be impossible to supply all the pilgrims with filtered water from the municipal works, but, at the same time, they were of opinion that the system should be extended to the outlying village of Daraganj. Connexions could be made from the pipe to stand-posts erected for use during the fairs. Suspicious wells to be closed and some trial *piaos* put up.

At the last meeting of the Board, the Government order giving effect to the rules under the Village Sanitation Act was read and recorded.

The income of the 151 municipal towns in the Punjab in 1895 was Rs. 44,04,983, and, as there was a balance of Rs. 11,25,690 from the previous year, the total sum available was Rs. 55,30,673. The amount spent on sanitary works rose from Rs. 11,85,311 in 1894 to Rs. 12,33,037 in 1895, but this includes Rs. 5,43,825 for conservancy establishment, and Rs. 2,77,889 spent on roads and bridges. On water-supplies, including the cleansing and repairing of the wells and tanks, Rs. 1,55,583 were spent, against Rs. 1,75,814 in 1894, and on drainage and sewerage the expenditure was Rs. 1,69,329, as compared with Rs. 2,13,563 in the previous year. The amount realised by the sale of manure and town sweepings, Rs. 1,39,434, shows a considerable increase; in 1892 the sum was Rs. 1,28,804, and this fell in 1893 to Rs. 1,13,733, again rising to Rs. 1,23,644 in 1894.

During the year the water-supply schemes for Umballa City and Delhi were completed; those for the towns of Pind Dadan Khan and Haripur were in progress; while those for Amritsar, Bhiwani, Dera Ghazi Khan, Ludhiana, and Sialkot were still being considered.

At Umballa (population 26,856) the scheme provides for the daily supply of 210,000 gallons to the city, and 37,500 gallons to the civil lines. The water is pumped from 20 deep wells, each 7 feet in diameter, at Handesra on the Tangri river, through an 8-inch main, to a service reservoir in the city. The supply for the civil lines is taken off this main before it enters the city, and is conveyed to two small reservoirs in the civil lines. From the reservoir in the city, which is capable of containing one day's supply, the water is distributed to 50 stand-posts placed in convenient situations.

At Delhi the water is pumped up from wells in the bed of the Jumna to a high-level reservoir, whence it is distributed through iron pipes.

The conserved area of the Kalka water-supply was partially fenced in. Good supplies of water have been brought by means of iron pipes to the villages of Paragpur and Duliana, in the Kangra district; the cost, which exceeded Rs. 6,000, was defrayed by certain philanthropic natives. The scheme for the extension of the Rawalpindi water-supply was completed. At Kohat, a spring, at Surdag, was improved by the construction of a reservoir, and excellent water is obtained from it by the inhabitants of the surrounding villages, and by travellers on the Kohat-Bannu road.

The drainage schemes for Ludhiana, Gujranwala, and Peshawar City (surface drains) were completed, and that for Delhi partially completed; the scheme for Lahore, and the construction of the main outfall sewer at Jhelum, were in progress, and schemes for the towns of Hissar, Hansi, Karnal, Ferozepore, Multan, Gurdaspur, Rawalpindi, Abbottabad, and 13 other towns were under consideration.

Several large drains and cuttings were made in different parts of the Gurdaspur district, in order to improve swamps and reduce the water-logging of the soil. In the districts of Karnal, Hoshiarpur, Jullundur, Ferozepore, Montgomery, Lahore, Sialkot, and Kohat arrangements were made for the distribution of rewards to headmen and others for services in connexion with the improvement of sanitation in their villages.

The members of the Sanitary Board met four times, twice in Lahore and twice in Simla. The following matters engaged their attention :—

(1.) The rules to be observed at the important fairs in the Punjab were discussed, and additions to, and alterations in, the existing rules were recommended to the Local Government for adoption.

(2.) The causes of the unhealthiness of certain tracts in the Umballa district and Kalsia State. It was resolved that the Sanitary Commissioner should undertake an inquiry, in communication with the local officers, reporting progress to the Board from time to time.

(3.) The combined drainage scheme for the city and cantonment of Rawalpindi.

(4.) The insanitary condition of Machiwara, a low-lying badly-drained town in the Ludhiana district. It was resolved that the arrangements made by the canal authorities for the improvement of the sanitary condition of the town were sufficient for the present.

(5.) The excessive fever death-rate in the province, due to water-logging. Proposals made by the provincial Sanitary Commissioner for obtaining the necessary statistical information were approved by the Board.

(6.) The severe outbreak of small-pox in the city of Multan. The Board passed a resolution to the effect that the Vaccination Act should be extended, not only to Multan, but to every municipal town in the province.

There has been no Sanitary Engineer appointed in the province as yet, but, as pointed out by the Chief Engineer of the provincial Public Works Department, specialists are not generally required to carry out the schemes for the small towns, and, when a scheme has to be carried out for a large town, there are always engineers, who have given much time and attention to sanitary works, available from the provincial service. As soon as one project is completed an officer of special experience and a staff more or less completely trained become available to commence another.

The income of the 19 municipal towns in the Central Provinces was Rs. 18,03,356, and, excluding sums spent on medical relief, vaccination, and miscellaneous objects, aggregating Rs. 75,231, a sum of Rs. 2,98,596 was spent on sanitary works, including Rs. 1,95,861 on conservancy, Rs. 50,449 on water-supply, and Rs. 32,586 on buildings. The chief works carried on during the year were the following :—

The extension of the Jubbulpore waterworks. This was begun in September 1894, and Rs. 2,09,167 of the Rs. 2,48,283, which the extension was estimated to cost, had been spent by the end of 1895. The following portions of the work have been finished: A straining tower at the reservoir, with a syphon over the dam from the reservoir into the tower. A 12-inch main has been laid from this tower to Jubbulpore. Distribution pipes varying from 3 inches to 12 inches in diameter have been laid in the city, civil station, and contonments, about 16 miles of pipes in all, and standards have been erected in the town and civil station.

At Wardha, the boring for water, referred to in last year's report, was continued until a depth of 90 feet was reached, when the scheme was abandoned. A complete estimate for the supply of the town with water, pumped from the river at Pownar, at a total cost of Rs. 2,07,057, was submitted in November 1895, and the foundation-stone of the work was laid by the Chief Commissioner in December.

At Bhandara investigations and experiments regarding a possible supply of water by filtration from the sandy bed of the river Wainganga, were commenced and are in progress.

At Harda two experimental wells were sunk and a supplementary estimate was sanctioned.

At Khandwa the water-supply works were in progress, and Rs. 95,708 were spent on them during the year.

At Hoshangabad a survey of the town was completed in connexion with a water-supply scheme.

Meetings of the Sanitary Board were held once in each division during the year, and the first Annual General Meeting took place in Nagpur in August.

At this meeting statements were presented to show :—

(1.) The works completed since the institution of the Sanitary Board and their cost, which was Rs. 1,92,640.

(2.) The works under construction, with estimates for works to be carried out in the year 1895–6, amounting to Rs. 22,206 from district funds and Rs. 29,222 from funds locally obtained.

(3.) The proposals and estimates for sanitary undertakings for 1896–7, to cost from district funds Rs. 26,312 and from other funds Rs. 27,842.

As regards the expenditure in 1895, the amount fell far short of the estimate on account of scarcity of funds. The expenditure incurred, Rs. 33,535, was mainly on account of the digging of new wells, repairs to old ones, and clearing of village sites.

The total estimated income of the 11 municipalities in Berar in 1895 was Rs. 2,41,338, and no less than Rs. 1,02,504 were spent on sanitary works, including Rs. 66,074 on conservancy, Rs. 25,944 on water-supply, and Rs. 10,486 on drainage.

No new work of importance was undertaken during 1895, but the year having been one of drought, the existing arrangements for the water-supply of the towns were tested at Akola, where it was feared that the Kapsi waterworks, not being quite complete, would fail after the prolonged absence of rain ; it was found, however, that there was sufficient water available to keep up a small supply for the city. At Amraoti the water-supply failed, and the Kalapani tank, which, it was believed, would give a good supply of water to the city, was empty, and wells had to be sunk in its bed. At Khamgaon the tank, which has hitherto been believed sufficiently large and good, was not filled, and the water-supply of the city was much reduced.

The drainage scheme of Amraoti has been remodelled on a scale within the means of the municipality ; plans and estimates are under consideration, but is has been decided to carry out the work gradually as funds permit. At Akola, the municipality, although funds are scarce on account of recent expenditure on the water-supply, are

doing all that they can to have the town drained. At Shegaon excellent drainage work is carried out steadily and persistently. At Akot and Ellichpur considerable proportions of the funds were expended in this direction.

The District Boards set apart Rs. 94,715 for sanitary works, and spent during the year, Rs. 32,979 on water-supply, Rs. 42,323 on conservancy, and Rs. 10,449 on drainage, making up 90·5 per cent. of the total sum allotted.

The District Sanitary Board met six times, once at each head-quarter station, and examined the result of recommendations made by the provincial Sanitary Commissioner. The recommendations had been carried out in a large number of instances and only want funds it is said impedes further progress. The question of a sanitary law for the improvement of village sanitation is being considered.

In 1895 there were, excluding Madras, 56 municipal towns in the Presidency, and the estimated income of these, in 1895–96, was Rs. 28,86,470, of which Rs. 16,23,540 were allotted for sanitary purposes. The sums actually spent in the nine months ending with December 1895, were Rs. 3,69,982 on conservancy, Rs. 1,58,139 on the improvement of town and village sites, Rs. 1,40,359 on the improvement of water-supplies, and Rs. 56,770 on other sanitary objects, making a total of Rs. 7,25,250, or only 44·6 per cent. of the allotment, leaving a sum of Rs. 8,98,290 to be spent in the first quarter of 1896. The municipal income of the city of Madras was estimated to be Rs. 16,83,360, of which a sum of Rs. 8,18,996, or 48·6 per cent of the total, was set aside for expenditure of sanitation. Of this sum, 36·0 per cent. had been spent by the end of 1895, including Rs. 1,90,816 on conservancy, Rs. 59,640 on the improvement of sites, and Rx. 17,540 on improvement of water-supplies.

While only 19·4 per cent. of the sum allotted by Municipal Committees for expenditure on water-supplies was spent during the first three-quarters of the financial year, 70·6 per cent. of the conservancy allotment was spent. The Sanitary Commissioner points out that it is far more difficult to get a municipality to spend money on improving the supply of water than in the disposal of sewage. The sewage is a nuisance, which must be got rid of in some way, whereas it is difficult to persuade a council that the water, which has been in daily use for many years, requires to be improved upon. Although it seems that disposal of night-soil and rubbish, after collection, is not carried out properly, except in a very few towns, it is hoped that the employment of the certificated sanitary inspectors, who are now available, will lead to improvement in this respect; meanwhile, the advantages of sewage farming are being impressed on the councils by the Sanitary Commissioner. At Madras, certain of the more glaring defects in connection with sewage farming operations carried on there have been remedied, but it appears that much remains to be done. At Tanjore the improvements to be effected should result in the sewage farm there becoming a model. At Erode sewage farming on a small scale was begun during the year. At Vizagapatam a sum of money has been set aside to start a farm, while at Cuddapah and Vizianagram proposals are receiving consideration. In the last-named town, it has been the custom to discharge much of the sewage untreated into a body of water, known as the Peddadcheruvu, resulting in a serious nuisance to the townsfolk; by the advice of the Sanitary Commissioner, a temporary sewage filter was constructed, which is acting efficiently. At Vizagapatam, where much of the sewage was sent direct into a back-water, a similar under-drained sewage filter was constructed; about 7,200 gallons of sewage are treated daily, and the filtrate is clear and looks like pure water.

The following works were completed and opened for the use of the public during the year:—

(1.) The Adoni water-works. The town is supplied by gravitation from filtered water reservoirs, but when only two of the three filter beds, 50′ × 40′ each, are being used, they must permit of filtration of the 230,000 gallons of water required, a little too quickly to accord with recently promulgated opinion, and the filtered water reservoirs are inefficiently protected from dust; these defects, however, which have been pointed out by the Sanitary Commissioner, can be easily remedied. Much of the cachment area has been bought up, and the Municipal Committee have been advised to acquire the remainder.

(2.) The Tanjore water works. Water is pumped up from an infiltration bed in the river Venar. It has been the custom to stop pumping on Sunday, the result being on that day the people make use of the old contaminated sources of water-supply, and the pipes of the new supply are liable to contamination by aspiration. These defects have been indicated, and it is intended to make a service reservoir to be filled by the surplus water pumped up; this will keep the pipes full and prevent aspiration.

The following were among the subjects which engaged the attention of the members of the Sanitary Board during the year:—

(1.) The water from Marlimund reservoir at Ootacamund having been shown by analysis to be bad, and samples taken from the bottom of the reservoir having been found to consist of masses of vegetable matter, it was advised that a new storage reservoir should be built, and that tracts of jungle should be excluded from the catchment area. As the matter presented considerable engineering difficulties, the Board advised the appointment of an engineer to prepare a a suitable scheme.

(2.) For Salem, where the supply of water is not only impure, but scanty, several schemes were proposed, and projects are still being considered.

(3.) For Cuddapah, the filtration of the water-supply, a pipe sewerage scheme, and a complete system of subsoil drainage were recommended by the Sanitary Commissioner and agreed to by the Board.

(4.) For Coonoor, it was recommended that investigation should be made into alternative proposed sources of water-supply.

(5.) For Bezwada, a water-supply scheme is still under discussion.

(6.) For Gudiyattum, a cheap project for water-supply from infiltration galleries in the sub-stream of the river was discussed.

(7.) For Calicut, alternative projects for a water supply were considered.

The estimated income of the district boards, for 1895–96, was Rs. 75,47,420, and of this, Rs. 6,96,428 were allotted for sanitary works, but, during 1895, only Rs. 3,57,775 were spent under the following principal heads:—On water-supplies, Rs. 54,940, little more than one-third of the sum allotted; on conservancy Rs. 2,36,576 or 70 per cent. of the allotment, and on improvement of sites Rs. 26,466, or 43 per cent. of the allotment. Although there has been an increase of Rs. 41,093 in the sum devoted to sanitary purposes, as compared with 1894, considerable differences in the amounts allotted by the various boards exist. The Boards of Tinnevelly and Godaveri, for instance, allotted 15·3 per cent. of their incomes, while the Boards of South Canara, Malabar and Nilgiris allotted only 3·5, 2·6, and 1·9 per cent. respectively; moreover, there is a great variation in the proportions of the allotment expended, although in this respect, also, Dr. King notes an increase. The Sanitary Commissioner, moreover, testifies to improvements in arrangements made for fairs and festivals in the districts.

In Coorg the amount spent on sanitary works was Rs. 12,423, of which the water supply works at Mercara absorbed Rs. 6,487. These works were not completed before the monsoon, so that the reservoirs could not be completely filled. So far, however, the people appreciate the water supply, and have subscribed Rs. 2,300 for the extension of the pipes along the Fraserpet Road, while the success of the scheme has caused other small towns to clamour for similar supplies. In one of these, Virajendrapet, Rs. 14,550 towards a scheme have already been subscribed by the inhabitants, and surveys were being made.

The Sanitary Board met once, in July, and the following matters engaged the attention of the members:—

(1.) The proposal for a water-supply scheme, made by the municipality of Virajendrapet; plans and estimates are to be submitted by the Executive Engineer.

(2.) A proposal to provide a supply of pure water to the small village of Boikeri, towards which the inhabitants had promised to subscribe Rs. 600.

(3.) A proposal to build shelters on the ghât roads for the coolies who travel over them; it was resolved to build five shelters, and to entertain an establishment to take charge of them.

(4.) A proposal made by the Civil Surgeon to introduce the sale of quinine at the Post Offices, was agreed to, and the Commissioner was requested to address the Local Government on the subject.

(5.) Schemes for the building of a lying-in hospital, for the construction of side drains in the main street of Mercara, and for the building of a lying-in ward and nurses' quarters at Virajendrapet, were brought forward for consideration and sanction.

(6.) The Civil Surgeon enquired as to the fate of the rules for the preservation of the health of the coolies employed on the coffee plantations, sent by the Chief Commissioner for revision and reconsideration of the Board. He was informed that the rules had been sent to the Coorg Planters' Association for their opinion, and that a reply had been received to the effect that no

opinion could be passed on these rules until the members of the Association had been given an opportunity to consider certain subsidiary rules which had drawn up by the Local Government; this reply of the Association had been submitted to the Local Government.

The total income of 168 municipalities in the Presidency of Bombay in 1894–5 was Rs. 47,49,303, and of this a sum of Rs. 21,50,827, or 45·28 per cent. of the whole, was set aside for expenditure on sanitary works. The sums spent, however, fell short of the allotments under all heads of expenditure, and only Rs. 18,21,963, or 84·71 per cent. of the allotment was used. Of the total, Rs. 8,69,219 were spent on conservancy, Rs. 4,96,543 on improvement of water supplies, and Rs. 2,15,979 on improvement of town sites. The income of the District Local Boards was Rs. 38,06,842, and of this Rs. 7,89,206 was assigned to sanitary works, but only Rs. 5,16,698 were actually spent, chiefly on improvement of water supplies, including the construction, cleansing, and repairing of tanks and wells, to which a sum of Rs. 4,76,202 was devoted.

The Bombay Village Sanitation Act of 1889, which provides for the contribution by the Local Board and the Provincial Fund of two-sixths and one-sixth respectively of the total cost of such schemes as provide for the improvement of village water supplies, &c., on the condition that certain of the villagers are competent and willing to assist in the supervision of their working, was introduced into 163 villages up to the end of 1825.

No new sanitary work of importance appears to have been undertaken during the year. At Surat only preliminary work on the water-works was carried on pending a decision of the High Court regarding a new house tax. At Ahmednagar, the plans and estimates for the first section of the water-supply works have been completed under the direction of the Sanitary Engineer; application for a loan has been made to Government, and it is hoped that the work will be completed during the current year. At Nasik, where the water supply is scanty and drainage very defective, the questions of a water supply and drainage are being considered. At Sukkur rapid progress on the water-supply works was made, and a drainage project is being prepared. At Ahmedabad, the sewage farm has been much improved, but more land is required, and what there is should be suitably levelled and laid out for broad irrigation.

The number of meetings of the Sanitary Board is not stated. Advice was given by the Board regarding a large number of projects, including the improvement of the water supplies at Dakor, Alandi, and Kirki; a scheme for the supply of Parel; the experimental drainage scheme for Ahmedabad; the drainage and sewerage of Yeola; a drainage project for Dhulia; and the question of house connections with the sewerage system at Colaba.

The grand total of the incomes of the towns and districts of Upper and Lower Burma in 1895 was Rs. 54,69,359; of this sum Rs. 19,87,857 were spent on the work of sanitation, including Rs. 3,37,133 on water supplies, Rs. 3,73,052 on drainage, and Rs. 7,40,722 on conservancy. No new work of any magnitude is reported to have been begun.

In Rangoon the Shone and Ault sewerage system is being gradually extended; during the year 401 house-connections were made, and 1,015 latrines were constructed. The reclamation of the east end of the town is being pushed on steadily.

In Moulmein the survey of the town has been completed, and levels of the drains obtained. The water-supply scheme is not yet begun. Alternative projects are under consideration; the one provides for the pumping of river water to a reservoir on a hill behind the town, whence, after filtration, it would be distributed by gravitation; the other provides for a reservoir in the Toungwin hills, about seven miles away from the town. The latter project appears to be beyond the means at the disposal of the municipality.

At Prome the filter gallery connected with the pumping station which has been abandoned for the past nine years, was put into working order and has been in use since May 1895. About 25,000 of the 30,000 inhabitants of the town are supplied with water from the hydrants.

The Sanitary Board's work continued to be restricted to the provision of suitable sanitary maps of the larger towns in Lower Burma.

General Remarks.

Revision of the Cholera Rules.—In concluding the report of their investigations into the outbreak of cholera in the Lucknow Garrison in July and August 1894, the Special Committee recommended that the practical certainty of the truth of microbic

infection should be used as the basis of the next revision of the rules regarding the measures to be adopted on the outbreak of cholera. Sanction was given by Government to the assembly of a committee composed of the Quarter-master General in India, as President, the Principal Medical Officer in India and the Sanitary Commissioner with the Government of India, as members, with Mr. Hankin, the Chemical Examiner and Bacteriologist, North-Western Provinces and Oudh, as associated member to consider the question.

A copy of the revised rules, the adoption of which was sanctioned by the Government of India on the 10th of September 1896, is printed as an appendix.†

Anti-Cholera Inoculations.—The anti-cholera inoculations, which were begun by M. Haffkine in 1893, have been carried out in Colcutta continuously, in Assam, and in various parts of the country under the general direction of M. Haffkine himself, to whom every assistance has been given by the Government of India and the local authorities concerned. As M. Haffkine has been busily engaged in Bombay on an inquiry into the nature of bubonic plague, he has been unable to furnish a complete statement of the results of the inoculations. So far as the tabulated numerical results received go, however, they are certainly very encouraging.

The Red Sea Pilgrim Traffic.—The following short summary of the facts concerning the Red Sea Pilgrim traffic and the outbreak of cholera at Camaran, is taken from the report of the Health Officer of the Port of Bombay, from the report of Dr. Vaume, Chief of the Camaran Mission, and from the report of Her Majesty's Consul at Hodeida and Camaran.

The number of pilgrims who left Bombay for the Haj was the second highest on record. The 26 veseels which left the port afforded accommodation, on the scale laid down by the Native Passenger Ships Act, for 17,056 adults, and 17,102 pilgrims, including 751 children under 12, and 223 infants under one year of age, were embarked. The vessels, which were of the usual class employed on the trade, were, on the whole, well ventilated, and provided for each pilgrim 9 square feet in the 'tween-decks and 6 square feet on the upper-deck. Only one vessel, the Turkish steamer "Abdul Kadir," required considerable alterations and repairs to enable her to carry a fairly large number of pilgrims under the provisions of the Indian rules. The luggage nuisance was less prominent than usual.

During the outward voyages the health of the pilgrims was fairly good, as there were only 484 admissions to hospital, and 61 deaths. The chief causes of admission were fevers, diarrhœa, dysentery, and injuries. As usual, the majority were admitted for bowel complaints during the voyage from Camaran to Jeddah. The most common causes of death at sea were, fevers (18), old age and debility (9), general debilty (6), dysentery (6), and phthisis (4); there was one death due to diarrhœa. During quarantine at Camaran, 147* pilgrims died, including 72*, whose deaths were attributed to cholera. From this it will be seen that in proportion to the time spent there, including special detentions, and not counting deaths from cholera, the mortality at Camaran was far higher than on board the ships, the relation being about 3 to 2.

On the return voyage, 17 vessels, with space for 12,874 adults, carried 10,472 persons to Bombay. The number of admissions to hospital on the voyage was 345, and there were 88 deaths, due chiefly to general debility, dysentery, and old age. The difference in the numbers who leave for, and return from, Arabia by sea is generally about 33 per cent.; in 1895 the percentage of "missing" was only 28.

Camaran.—The Haj of 1895 took place on the 4th of June, and the lazaret at Camaran was opened on the 20th of the preceding December. The earliest pilgrim steamer was the "Java," which arrived on the 29th January from the Dutch Indies. The first Indian pilgrim steamer was the "Mohammadi," which reached Camaran from Bombay on the 1st of February. Subsequently 36 vessels, including 9 dhows, brought pilgrims to Camaran to undergo quarantine. The total number of pilgrims landed was 24,062, including 10,010 Indians and 880 Afghans. The quarantine imposed was from 24 to 48 hours in the case of pilgrims from Persia and Hadramaut direct, five days for pilgrims from Java and the Straits (until cholera broke out at Camaran), and 10 days for pilgrims from Indian ports. The weather was exceedingly unhealthy throughout the season, with cold mornings and very hot days, and the mortality among the pilgrims detained in the lazaret was 6·9 per 1,000, as compared with 2·23 in 1894.

* In the British Consul's report the figures are 162 and 67.

† Not reprinted.

Cholera at Camaran.—The evil fortune which attended the passengers of the "Hosseinee," who were obliged to return to India without having accomplished the Haj, has drawn a larger share of well-merited attention to the condition of affairs at Camaran than this has hitherto received.

Cholera developed among the pilgrims of three vessels from Bombay during their periods of quarantine, and the circumstances were very remarkable.

During 1895 the town and port of Bombay were unusually free from cholera. Only 90 deaths were registered during the year, a smaller number than in any of the previous eight years except in 1886, when only 19 deaths were recorded. During the first four months of the year there were only six deaths, as low a number as has ever been recorded; three occurred in January, one in March, and two in April. The three steamers, the "Mohammadi," "Jubeda," and "Hosseinee," are among the very best pilgrim liners in the trade, and their sanitary condition was excellent when they were examined prior to the embarkation of the pilgrims. On the voyage to Camaran they touched at only one intermediate port, namely, Aden, where there was no cholera.

The "Mohammadi" left Bombay on the 6th March and arrived at Camaran on the 16th. Three deaths occurred on the voyage, ascribed, respectively, to debility (8th March), pneumonia (8th), and pulmonary consumption (15th). There were 818* pilgrims on board, who were landed and placed in camp under the care of Dr. Halim Bey. On the 23rd March, seven days after arrival and 17 after leaving Bombay, a Malabari died, and two others were seized with diarrhœa. Dr. Vaume writes:—

"These were serious cases, but not yet typical it is true, yet they were sufficiently pronounced for the purpose of observation."

Cholera was declared to be present on the 24th, and 15 days' extra quarantine was imposed. Cases of cholera continued to occur, with resulting imposition of fresh periods of quarantine, until the 7th of April. The pilgrims were re-embarked, and left on the 23rd April for Jeddah, where they were detained for another five days before they were allowed to leave for Mecca. Regarding their stay at Camaran, Dr. Vaume writes:—

"These pilgrims remained in the lazaret 39 days; cholera had raged during 17 days, attacking 31 persons, 27 of whom were pilgrims; 29 died, of whom 25 were pilgrims; the other victims were a Danakil working as night-man, two soldier guards, and one soldier in charge of the cordon. Besides these, 28 pilgrims died of various diseases, and two soldier guards of dysentery. From this resumé I observe two things, tardy appearance of the disease, and its localization at the outset among the Malabaris, who came from Calicut."

The S.S. "Jubeda" left Bombay on the 16th March, and reached Camaran on the 25th. There were 1,006† pilgrims on board. Three deaths occurred on the voyage, two of old age on the 22nd and 24th March, respectively, and one of pulmonary phthisis on the 23rd. The landing of the pilgrims was deferred until the 26th March, when they were encamped and placed under the care of Dr. Boumbouras. The health of the prisoners during the first few days in camp was excellent, but during the night of 29–30th March four Afghans were "almost simultaneously" seized with cholera. Cases occurred until the 21st April; 57 individuals were attacked, and 48 died. "The course of the epidemic," writes Dr. Vaume, "left the impression that there was some "general cause operating continuously, but not showing itself, except at measured "intervals according to the degree of individual resistance to the disease." The "Jubeda" left Camaran on the 10th of May for Jeddah, where the pilgrims do not seem to have been further detained.

The S.S. "Hosseinee" left Bombay on the 10th and arrived at Camaran on the 18th April. During the voyage no death occurred, and no pilgrim required medical treatment. The number of pilgrims is stated on the ship's bill to have been 697, but the number landed is stated by the Consular Agent to have been 706. These pilgrims were placed in camp under the care of Dr. Moschidis. Cholera appeared in the camp on the 24th April, the 6th day after arrival and the 14th after departure from Bombay. The disease was confined, until the 17th May, to Malabaris. Cases continued until the 27th May, when it was evident that, if further quarantine were imposed, the pilgrims must be too late for the Haj. Finally, after much telegraphing, the pilgrims resolved to return to India, and the "Hosseinee" left for Bombay on the 1st of June. Dr. Vaume notes that "nearly all the cases on the steamer "Hosseinee"

* According to the Consul's report; 781 according to the ship's books.
† 1,046 according to British Consul, and 1,041 according to Dr. Vaume.

" had their origin in the same town as the earlier cases on the steamer " Mohammadi," " viz., Calicut on the Malabar coast," and he concludes his account of the " Hosseinee's " detention as follows :—

" To sum up, cholera raged from the 18th April (N.S.) to the 25th of May; it attacked 21 persons, 16 of whom died, viz., 3 Bengalis (1 was cured), 17 Malabaris out of 119 (4 were cured), and a native guard. This epidemic is remarkable alike for its persistency among the Malabaris, the somewhat long period that elapsed between the cases as well as for the acuteness of the attacks. It has also been interesting in that it has furnished proof as to the origin of the disease. Moreover, in the Mervani camp, in which the pilgrims of the " Hosseinee " were lodged, there has never been cholera; it would be childish on the part even of the bitterest enemies of our lazaret to contend that Camaran gives cholera in certain years, especially to inhabitants of Calicut and its neighbourhood. The utmost subtlety would fail to prove that the Indians from Malabar got the contagion at Camaran. I am well aware that the legend is wide spread in India, and I have read several diatribes in the Bombay papers, and can understand how it was that the idea enters into the Indian pilgrim's head to exclaim the second day after being lodged in our lazaret, 'I arrived here quite well, but your water has given me diarrhœa.' A little more imagination, and it would be said that Camaran is situated on the Hooghly."

Dr. Vaume is of opinion that the Malabar pilgrims brought cholera from Calicut on the Malabar coast. The population of the district of Malabar is considerably more than two-and-a-half millions. The number of deaths that occurred from cholera in 1894 was 1,145, of which 135 were registered in Calicut. Most of the deaths occurred in the earlier part of the year. In 1895 only 429 cholera deaths were recorded in the district, and the cholera mortality was ·2 per 1,000 of the population, as compared with 1·5, the mean of the five years 1890–94. In Calicut town there was only one death from cholera registered during the year, on the 3rd of February, and the rural circuit of Calicut was entirely free from cholera throughout the year. It is strange, then, that Malabaris should bring cholera from a place in which it was practically non-existent.

This is how Mr. Vaume explains the absence of the disease during the voyage :—

" The question, however, is not an easy one; the following is the position: Three pilgrim ships arrive at Camaran from Bombay after a voyage of 9 or 10 days. The captain and the doctor say that nothing suspicious has occurred during the voyage; the ship's papers bear out their statement, and, on the whole, the thing appears probable. Between the 5th and 7th day after the pilgrims have landed cholera appears among them. An unreflecting person would say, therefore, 17 days' incubation. Let us pass over such a crude manner of reasoning, and look more closely into the matter, and in a manner which is apparently more probable.

" Dr. Koch assures us that he has found in great numbers and alive in the waters of the marshes in the vicinity of Bombay certain vibrios which have since spread. This vibrio is the cholera germ. Indians who frequently use those waters absorb them in masses without getting cholera. Owing to this circumstance it is said that the vibrio is harmless; it will be agreed, however, that there may be in the human system certain antidotes entirely unknown elsewhere which it is supposed do exist there; in fact as the vibrio does not find either in the stomach or the intestines the requisite conditions, investigation has only been directed in recent times to ascertaining what are the requisite conditions it vegetates in this domicile without acquiring that virulence which alone discloses its existence and attracts our attention. It exists then in a latent state it will be said. So be it; but the interesting point for us is to discover and determine the circumstances which put an end to this latent state and convert the common inmate of the gastro-intestinal canal into a terrible poison which used formerly to cause those deadly epidemics during which the existence of a great nation appeared at time to be stopped in its course. Metchnikoff appears to have clearly pointed out the path to follow in these investigations. He has shown that the nature of the gastro-intestinal coating modifies the vitality of the comma bacillus in such a way as to make the most harmless virulent and the most virulent harmless. His experiments, carried out with that precision and ingenuity of which that unique mind has given so many proofs, have not yet been disproved, and without accepting them as definite and as absolutely correct, they may at least be taken as a basis, for we should be certain of treading on almost firm ground. I can, therefore, well imagine that Malabaris who left their country where cholera had raged with great severity towards the end of 1894, carried cholera germs alive in a latent condition in the intestines, that these germs under influences unknown to me became virulent, and, lastly, that cholera appeared among them at Camaran. But again, has it been quite proved that these influences exist at Camaran? Finding that the water in the cisterns had become after a certain time as it were thick to the touch and weedy, I prevented this water from being given to the pilgrims of the " Hosseinee," and I, daily, had the water which was taken from the wells supplied to them. The result was the same. How glad we should have been to have had a laboratory this year, and a competent assistant. I do not say that I would have been able to lay before you any conclusion, but I should not at least have been reduced after so much writing to leave matters in such doubt.

" Do not think that I am satisfied with this hypothetical explanation. Another corollary, however, connected with it, which throws light on obscure points, comes to my mind. It is still less definite and difficult to formulate; I will, however, endeavour to explain it. Let it be granted according to the theory enunciated at the Buda-Pesth Congress of 1894, that two elements are

required to bring about cholera, one which is known, viz., the comma bacillus, the other still unknown, which is due to surrounding circumstances, the nature of which we do not know.

"The ancients used to call it the epidemic genius, and we endeavour to discover it by limiting more and more the known quantities of the problem. The great role indeed of modern science is to explain in a scientific manner the vague and striking terms of the ancient observer. I imagine that those conditions can be found to exist, why and how I cannot say, at Camaran and in the Hedjaz at the same time. And as the journey of the Indians who go direct to the Hedjaz is performed under infinitely better conditions than the great masses of the pilgrims enjoy who come to Camaran, I do not see why the appearance of disease among them should not be a little later than at Camaran. Although I admit that this way of looking at the question possesses no value, yet I lay it before you. In this way the almost simultaneous appearance of cholera at Camaran and in the Hedjaz might be explained without connecting one with the other. It might, perhaps, also be thought that infection is carried by the wearing apparel, and in that case it might be argued that disinfection was not properly done. I have often explained how it is done, and I need not refer to the matter here. However, to make disinfection still more efficacious to render it almost ideally perfect, we want at least another moveable stove for work, especially in the camps that have contagion. We also require a larger staff. It remains for me to address you on these points, but I must remind you, in the first place, that cholera showed itself among the staff, and this is the strongest reason in favour of the necessity of shutting off the divisions from each other in a proper manner."

This explanation is a little difficult to follow, and it certainly reads like an admission that the potent cause of the cholera epidemics exists in Camaran and the Hejaz, which, it must be admitted, is the simplest way to explain the facts. The probability of prolonged latency is negatived by all experience of cholera, but if such latency could exist, quarantine is evidently a vain precaution! It appears, however, that Doctor Vaume is sceptical as to the absence of cholera on the pilgrim ships; and the fact that the numbers of pilgrims landed generally differ from the numbers declared to have been embarked, lends justice to his remark, after comparing the figures. "A portion, "therefore, of the effective strength may disappear without our being in a position to "discover."

The urgent wants of Camaran are arrangements for a supply of good drinking water and proper accommodation for the pilgrims. In its present state this quarantine station is evidently not only useless for the purpose for which it is intended, but may be a source of danger to the Hejaz.

Researches by the Special Assistant.—Most of the work which was conducted in the Biological Laboratory attached to the office of the Sanitary Commissioner with the Government of India during the past year, was devoted, 1st, to a series of experiments dealing with the question of the action of snake-venoms as primary hæmic or primary nervine toxins, and, 2nd, to experiments in regard to natural and artificial immunity to the action of snake-venoms, and to the protective and curative action of antivenenes.

The results of the first series of experiments will form the subject of a paper in the forthcoming number of "Scientific Memoirs, &c.," and appear conclusively to indicate that cobra-venom, at all events, has a very marked action on the blood of susceptible animals, leading to very rapid solution of erythrocytes and more gradual reduction in the respiratory property of the hæmoglobin, and that variations in susceptibility to the toxic action of the venom are accompanied by corresponding variations in the degree to which the latter is capable of giving rise to hæmic changes.

The second series of experiments has already been dealt with in a special report, and the data furnished by it appear to justify the following conclusions:—

(1.) The serum of the blood of animals, which have been artificially immunised to the action of lethal doses of snake-venoms by means of habitual and cumulative treatment with the latter, unequivocally possesses antidotal properties, and hence may fairly be denominated antivenene.

(2.) The term antivenene is, however, of generic, not specific value, for the antidotal material contained in the blood of animals which have been artificially immunised against colubrine venom is inert against viperine venom and *vice versâ*.

(3.) The amount of active antidotal material in the blood of artificially-immunised animals would appear to bear a definite and direct relation to the amount of venom against which immunity has been established, the actual quantity of antidote present in the system in any case being apparently little in excess of that requisite to equilibrate the toxic action of the amount of venom, under the influence of which it has been elaborated.

(4.) In consequence of this, treatment with crude antivenene is only adapted to secure recovery in cases where minimal or, at utmost, slightly supra-minimal lethal doses of venom are opposed by relatively large doses of the serum of highly-immunised animals.

In order to secure recovery after the access of any given dose of venom to the system, the quantity of antivenene which must be employed will necessarily vary with the degree of immunity which has been established in the animal from which it has been derived. In cases where the degree of immunity has been very high, relatively limited quantities of antivenene may be capable of conflicting successfully with small doses of venom; but, as in order to conflict successfully with any given dose, an amount of antivenene equivalent to the entire, or almost entire, antivenene content of the blood of an animal which has been immunised against a like dose is necessary, so in dealing with large doses of venom the amount of the remedy requisite to secure recovery must almost inevitably become prohibitive, and treatment with crude antivenene would probably be little better than treatment by transfusion of blood.

(5.) Treatment with crude antivenene, more especially in combination with other remedial measures, such as ligature and free incision and injections of solution of bleaching powder or gold chloride at and around the site of injury, may, therefore, be of some practical value in dealing with cases in which minimal lethal or slightly supra-minimal lethal doses of venom are in question, but, unless the really active constituent can be separated from the rest of the serum, its curative value must remain strictly limited.

(6.) The superiority of antivenene over other remedies in dealing with small doses of venom lies in the fact that its action is not a purely local one, but one which continues to be exerted subsequent to absorption into the circulation, so that it is capable of dealing with venom which has been already absorbed, and may therefore be an important aid to means which only act locally in reducing small lethal doses of venom to sub-lethal ones.

(7.) While the serum of the blood of animals which have been artificially immunised possess antidotal properties in relation to the venom in connection with the action of which the immunity has originated, this is not the case with the serum of the blood of the snakes which produce the venom, and consequently the natural immunity of venemous snakes to the action of their own venom cannot be essentially dependent on any process of auto-inoculation, or, in other words, on the constant and normal presence in their blood of any material of the nature of the antivenene elaborated in the bodies of artificially immunised animals.

(8.) The protective effect attending the introduction of antivenene into the system is a very transitory one, whilst that attending the habitual introduction of venom is persistent over prolonged periods, and therefore, whilst in the latter case the protection would appear to be dependent on persistent, reactive, systemic manufacture of an antidote, in the former it is seemingly merely dependent on the introduction of a ready-made antidote, which, because it is a blood derivative, is capable of remaining for some time unaltered within the system.

(9.) The ingestion of large quantities of cobra-venom, either habitually or on a single occasion, neither necessarily induces any toxic effects nor any appreciable protection against the action of the venom when it enters the circulation.

(10.) Mature specimens of the common mungoose certainly may be characterised by a relatively high immunity against the action of both colubrine and viperine venoms, but in the meantime it remains uncertain whether the exemption is of hereditary or acquired character.

The systematic investigation of choleraic materials has been continued and has served to confirm the conclusion that, in so far as Calcutta and the neighbourhood are concerned, cholera is either an exceptionally rare disease or one which is not necessarily characterised by the presence and prevalence of any one species of vibrionic organisms within the digestive tract, and has yielded additional evidence that there is no scientific ground whatever for the assumption that all the vibrionic forms associated with cholera are mere varieties of one and the same species, and that any such assumption can only be regarded as an arbitrary attempt to force facts to agree with popular beliefs.

It has farther been ascertained that vibrionic organisms, belonging to the same group as those which are ordinarily associated with cholera, may abound in the intestinal tract of fishes both in health and disease, and may occur in bodies of water quite apart from the presence of any choleraic disease in the vicinity. The entire mass of evidence afforded by the phenomena of cholera in Calcutta appears thus more and more to favour the belief that, in so far as vibrionic organisms are casually related to the disease at all, it is not because they are capable of giving rise to a specific toxin within the intestinal tract, but because, under certain conditions, they can do so in the environment. In

other words the evidence goes more and more to show that Pettenkofer's original theory was essentially correct, and only requires to be modified in so far that the processes occurring in the environment are to be regarded as processes of manufacture of a toxin, and not of mere maturation of germs.

In addition to the above systematic investigations, casual work of the following nature has also been conducted:—

I. Examinations into the nature of the schizomycete population of samples of water and milk as possible causes of the occurrence of cases of cholera.

II. Determination of the nature of the morbid conditions accompanying the destructive blight of *Areca catechu*, which has been so prevalent of late years in Eastern Bengal.

III. An investigation into the nature of the various species of *Uredinous fungi* giving rise to "rust" in cereal crops in India; and experiments in regard to a possible intermediate host for one of them.

IV. The determination of the true nature of the active principle of the ferment ordinarily employed by the natives of the Eastern Himalaya.

V. Determination of the nature of various vegetable blights affecting tea and other economic and ornamental plants in India.

LIBRARY OF THE BOMBAY BRANCH OF THE ROY. ASIAT.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1895.

(*Surgeon Lieutenant-Colonel W. G. King.*)

Vital statistics.

The population under registration during 1895 amounted to 33,605,784 according to the census, and 36,137,558 according to the estimated population. Areas inhabited by a total of 2,036,044 souls were not under any registration system during the year. This populated consisted of hill tribes, inhabitants of zemindaries, and certain islands on the west coast, where it has not yet been possible to graft this refinement upon existing systems of Government.

Births and Deaths.—The birth and death rates for the whole Presidency were 27·0 and 18·2 per 1,000 respectively. In the following table these are compared with the rates for the previous 14 years:—

Year.	Birth-rate per 1,000 of estimated Population.	Death rate per 1,000 of estimated Population.	Years.	Birth-rate per 1,000 of estimated Population.	Death-rate per 1,000 of estimated Population.
1881	24·4	15·8	1889	26·3	20·1
1882	24·9	15·8	1890	26·8	19·5
1883	25·6	17·9	1891	27·3	22·0
1884	26·4	21·2	1892	24·6	21·8
1885	25·9	19·8	1893	26·1	18·7
1886	26·5	17·6	1894	26·4	19·0
1887	26·5	18·9	1895	27·0	18·2
1888	25·7	18·4			

The birth-rate is, with the exception of that for 1891 (27·3), the highest on record; the death-rate is the lowest on record since 1886.

Remembering that Mr. Stokes' standard for the birth-rate of the Presidency is 42·45, and Mr. Stuart's 52 per 1,000, it might at least be hoped that fairly careful registration would result in a birth-rate being shown of about 40 per 1,000. The following districts, however, reported rates below 30 per 1,000:—

Anantapur	29·9	North Arcot	28·5
Trichinopoly	29·5	Vizagapatam	26·7
Coimbatore	29·1	Nellore	26·5
Tanjore	29·1	Gódávari	24·3
Cuddapah	28·7	Malabar	24·0
Nilgiris	28·5	Ganjám	17·3

There is no reason to believe these rates result otherwise than from defective registration; although in the case of the Tanjore district, the considerable fluctuation of emigration and immigration which has taken place there for some years past cannot fail to have had some influence.

In the case of municipalities, there can, however, be little real excuse for defective registration. It can only result from a want of appreciation of the importance of the matter by Municipal Councils in enabling both Government and themselves to arrive at a just conclusion as to the efficiency of efforts employed to raise the sanitary condition of the people. Indeed, there is still great reluctance on the part of Municipal Councils to prosecute persons who fail to report births and deaths, and it is still the practice in several municipalities to trust to the information gained from peons who, having ascertained cases, give the people forms and invite their attendance at the office. Under such a system, if the peon fails to find a case, the event is not reported, as no action is likely to be taken by persons who are aware that no penalty is probable if they neglect this requirement of municipal law.

Of a total of 57 municipalities, 2 report birth-rates over 45 per 1,000, 22 over 35, 20 over 30, and 13 below this. Of those below 30, Cuddapah has, with reference to prevalence of malaria, a reason for absence of fecundity; but there would seem to exist no valid excuse in the case of Madura (29·0), Cocanada (20·2), Chicacole (21·6), and Berhampur (24·2). In the case of Cocanada, special representations were made to the municipality and the Collector of the district as to the neglect of registration during the year, with the result of ultimately securing some improvement in working,

but too late to exhibit any effect on the total statistics for the year. Chidambaram was shown by the last census to be undergoing decrease of population; but, granting this is so, I cannot regard the birth-rate of 24·0 otherwise than with suspicion, especially as the decrease has occurred less gradually than might reasonably be expected. Thus, in 1893 the rate was 29·9; in 1894 28·5, and in 1895 24·0.

In 20 municipalities death-rates show increase when compared with last year; but it must be remembered that 12 of these also show a marked rise in the birth-rate. This means, in short, that increased attention has been paid to registration generally.

For every 100 boys there were 95·8 births of girls registered; for every 100 deaths of males there were 95·4 deaths of females.

The infantile mortality of the Presidency was at the rate of 162·3 per 1,000 of births; but, as this rate is very far exceeded in towns—making allowance for the greater mortality that might be expected—the chances are that it is much lower than the truth, and that numbers of infants are buried without registration. Lest I be misunderstood here, I would state that there is no reason to think female infants are got rid of as suspected in other parts of India. On the opposite, Madrasees, though not appreciating female births, are, as a race, most devoted to, and careful of, their children. If there be truth in my opinion, the result must be due simply to the tendency for deaths of infants being held as of less importance than adults, and, consequently, more likely to escape observation of subordinates responsible for registration. The rate I obtained as a standard from 23 not abnormally unhealthy municipal towns in 1894 was 176·25 deaths per 1,000 of births.

I need hardly remark that a most delicate test of the sanitary state of towns—especially of the cleanliness of the soil of their sites—can be obtained by studying the rate of infantile and child mortality. The higher figures point just as conclusively to the towns possessed of sewage-sodden soils, or, what amounts to the same thing, filth-contaminated soils with fluctuating and high sub-soil water levels, as the actual sanitary survey does. Thus gauged, the sanitary state of municipal towns must be considered as far from satisfactory, although, as remarked in a former report, infantile mortality is doubtless aggravated by ignorant domestic hygienic and medical care.

There was a total of 658,719 deaths for the Presidency. These were returned under the following heads:—

	Percentage of deaths.
Cholera	3·2
Small-pox	0·8
Fevers	42·1
Dysentery and diarrhœa	3·6
Injuries	1·6
All other causes	48·7

The ratio per 1,000 of the census population of these various deaths causes will be found in the Appendix Statement No. 17.* But to form any accurate idea of the degree of prevalence of these diseases when compared with former years the totals must be reckoned upon the estimated population. Regarded solely in the light afforded in the tables referred to, it will be found that I should have to account for a rise in the mortality from fevers and "all other causes" from 8·0 and 9·3 in 1894 to 8·3 and 9·6 in 1895 respectively, whereas the increase is, in all probability, but ·1 in each case. Small as the difference between the two calculations is, namely, ·2 per 1,000 of the estimated population, it would represent in the Presidency that 13,500 deaths had occurred more than the probabilities of the case would warrant:—

Year.	Birth-rate per 1,000 of the estimated population.	Death-rate per 1,000 of the Estimated Population.						
		Cholera.	Small-pox.	Fevers.	Dysentery and Diarrhœa.	Injuries.	All other causes.	Total.
1891	27·1	2·9	1·2	7·1	1·0	0·3	9·3	21·8
1892	24·4	2·3	1·3	8·1	0·9	0·3	8·8	21·7
1893	25·9	0·9	0·8	7·3	0·7	0·3	8·5	18·5
1894	26·1	1·2	0·3	7·6	0·7	0·3	8·8	18·9
1895	27·0	0·6	0·1	7·7	0·6	0·3	8·9	18·2

* Not reprinted.

These figures, however, show that, whilst there has occurred a slight increase under fevers and "all other causes" in the rates, there has been a satisfactory decline in the prevalence of small-pox, cholera, dysentery and diarrhœa. Taking into account the higher birth-rate registered, and, remembering that this would operate adversely upon the total death-rate until the period of risk to infantile life is passed, it may be concluded that, although no decided improvement in the general health of the population can be demonstrated, the year was, on the whole, healthy, and compared favourably with the average of the preceding quinquennium.

Chief Diseases.

Cholera.

In the year under review a total of 21,172 deaths from cholera occurred, against 43,427 in 1894. In the first month of 1895 cholera was present in the following 13 districts:—

1. Chingleput,	6. Malabar,	10. South Arcot,
2. Coimbatore,	7. Nellore,	11. Tanjore,
3. Ganjám,	8. North Arcot,	12. Tinnevelly, and
4. Madras,	9. Salem,	13. Trichinopoly.
5. Madura,		

The districts of Madura, South Arcot, Tinnevelly and Tanjore were affected with cholera throughout the year.

The districts yielding the chief mortality from this cause were Tinnevelly (4,649 deaths), South Arcot (4,307 deaths). Both districts have water-supplies liable to contamination in a very marked degree: tanks and irrigation channels that run through large tracts of country and pass villages *en route* being the chief sources of water-supply. As illustrating how cholera may be conveyed by irrigation channels (of which there is ample proof) even when not subjected to the defilement incident to passing a village, I may cite a case that occurred a day previous to my last inspection of Palamcottah. A native was brought in from the rice fields in a state of collapse. He had undergone all the usual symptoms of vomiting and purging in his field, over which the surplus water passed to the irrigation channel at a lower level. In a widely-irrigated tract of country it may well happen that mysterious cases of cholera may be thus originated, in that the irrigation water is used for drinking and "other domestic purposes" by all villagers.

In 57 municipalities a total of 1,447 deaths from cholera were registered. In nine of them the deaths did not exceed 10 in each case. The bulk of the mortality was distributed between Trichinopoly (290), Chidambaram (216), and Madras and Periyakulam (115 each).

Small-pox.

The presence of this disease was reported in all districts, but the total deaths for the Presidency did not exceed 5,111, or 0·1 per 1,000 of the population; or, when reckoned on the estimated population, the rate was 0·1 against 0·3, 0·8 and 1·3 for the three previous years. The district of Malabar, which has been long notorious, showed the decreased mortality of only ·03 per 1,000. Anantapur, Bellary and Kurnool returned the highest rates, namely, 0·5, 0·6 and 0·6, respectively. The deaths of children below one year and 12 years amounted to 1,111 and 1,966, respectively.

From 38 municipalities 292 deaths were reported, or a total of 0·17 per 1,000 of their united populations. In Guntúr and Vellore the rates per 1,000 were 1·3 and 1·2 respectively. Of towns reporting the presence of small-pox, Madras and Tuticorin registered a mortality of only ·006 and ·004 respectively.

Fevers.

A total of 277,337 deaths were registered in districts and municipalities from fevers. The district of Vizagapatam showed the high rate of mortality of 18·2 from this cause, or 4 per 1,000 over and above that registered last year, which again was an increase on the previous period. There is no reason to think this implies any actual increase of incidence of fever in this district. But even this high rate is exceeded by that recorded for the Nilgiris, namely, 19·2 per 1,000 of the population. Certain parts of the Nilgiris are malarious and parts of Vizagapatam are markedly so; but in these instances the increase must be regarded as due to greater attention to registration by the Revenue officers, coupled with ignorance of the subordinates employed. Thus, if the statistics for Vizagapatam be accepted, it must be supposed that only 2·5 of the total mortality of 20·7 per 1,000 was due to any cause but fever, and, as to the Nilgiris, that all but 5·7 per 1,000 was so brought about, whilst although undesirable, the total death-rate (24·9) is not so great as to lead to the suspicion that a large

increase over normal mortality of the locality had occurred from one special disease. Cuddapah and Kurnool, both notoriously malarious districts, follow with a death-rate from fever of 16·0 and 15·1 per 1,000 respectively.

In the case of municipal towns, Cuddapah, as formerly, exhibits the highest rate (18·3) from this cause, followed by the chief town in the Presidency, namely, Madras, with 14·2 per 1,000.

Dysentery and diarrhœa.

A total of 23,937 deaths were recorded from these causes. The rate for municipalities is markedly in excess for districts as a whole, namely 3·4 per 1,000 of population against 0·7 per 1,000. Even making allowance for indifferent registration, I consider the result sufficiently striking in pointing to the influence of the usual concomitant of communities living under the evil hygienic conditions found in most of the municipalities up to date, namely, foul and damp soil, and water subject to fæcal contamination; where to these conditions the use of brackish water is added, the incidence of diarrhœa and dysentery becomes greater, for example, at Vizagapatam Karúr, and Tuticorin, where the rates range from 10·3 to 7·6 and 6·3 respectively.

Suicides, injuries, &c.

The practically unvarying proportion of injuries and suicides, namely, 0·3 per 1,000 of the population, was returned. This implies a total of 10,357 deaths from these causes arranged as follows:—

Suicides	1,913
Wounds and accidents	6,248
Snake-bites and killed by wild beasts	2,196

Sanitary Works.

Municipalities.

During the year, the Special Committee of the Legislative Council held numerous meetings for discussion of the various proposals suggested to Government for the revision of Act No. IV. of 1884, under which all the municipalities, with the exception of Madras town, which has a special Act, are administered. The result of the committee's work was the incorporation of several important sanitary measures. Had the country possessed a completely organised and equipped Sanitary Executive Department, it would, doubtless, have been an easy matter to have made several further improvements; but, even as they stand, the additional powers that are proposed, in respect to food and water protection, the combating of infectious diseases, and improvement of administration must prove in the near future of very great advantage in stimulating general sanitary advance. The revised Bill was at the end of the year still under criticism by the Legislative Council, but it is hoped, before the issue of the next annual report from this office, the new Act will be in operation.

In last year's report, I called special attention to the very backward condition of the municipal towns of the Presidency in the matter of conservancy, and suggested that important as the subject of new and protected water-supplies was, it must be almost regarded as a refinement to provide at a cost of some lakhs a town with a water-supply, knowing that the simple question of night-soil removal was attended to in the most perfunctory manner, and that, even after the admission of water, no improvement in this special respect could follow, in the absence of any intention to adopt the "water carriage system." Hence, I argued that it was a mistake for municipal councils to consider that the borrowing of money for sanitary works should be confined solely to provision of water and sewarage works. I then suggested that the Sanitary Board should consider the subject of how sewerage of the towns now provided was likely to be conducted in the future, so that the pushing forward the completion of conservancy might be entered into, it being obvious that should "water carriage" be ultimately adopted in the town, it would not be advisable to press the acquisition of special plant when it might be required to be shortly discarded. Government, having thereupon referred the question to the Sanitary Board, decided that in view of the indebtedness of towns lately provided with public water works and the probable rate of introduction of complete sewerage schemes, it would not be necessary to retard provision of special plant for conservancy of towns other than Ootacamund and Cuddapah, both being likely to be provided with underground sewerage at an early date. Since then the Government has directed that full estimates for the correct conservancy of each municipality should be framed. This, I consider, a measure likely to prove of benefit of a most comprehensive and radical nature.

In consideration of the high rate of expenditure on account of carting and the very filthy process involved, I trust that in the larger towns it will be possible, in the absence of underground sewerage systems, to utilize the Shone ejector method for despatch to depôts of night-soil as practised in Warrington, England, in combination

with destruction of refuse by incineration in localities where its sale is not remunerative, or disposal is attended with doubtful sanitary conditions.

Rubbish incineration was a favourite method of disposal of town rubbish in this Presidency twenty years back, and there are to be found in several municipalities incinerators of the old pattern, for the most part, however, neglected, or only used for ocular demonstration to inspecting sanitary officers of the process not having been quite forgotten. This disuse has been in part due to increasing use of town rubbish by ryots to whom it is sold, and to the fact that in wet weather such incinerators were useless. So far as India is concerned, the incineration process can only be said to have just passed through the experimental stage. Hence rapid adoption cannot be expected, nor is it universally necessary; but there are obviously localities where incineration offers the only solution of rubbish disposal. Calicut is an example of a municipality where both rubbish and night-soil disposal present unusual difficulty. It is further a town where the distances to be traversed are very heavy. Under these circumstances, in 1893, I advised the municipality to arrange for the conduct of their conservancy by the aid of a tramway and to incinerate their rubbish, and manufacture poudrette for export to the planting community in the neighbouring Wynaad Hills. The municipality pressed the question of the tramway energetically, and have, with the consent of Government, entered into an arrangement. The making of poudrette still, however, has not been effected, owing apparently to the non-erection of the experimental incinerator. In Masulipatam, a Silchar incinerator was duly erected during the year. In the town of Madras the difficulties attending the disposal of rubbish has reached an acute stage. The municipality collects the rubbish in open carts in which also large amounts of human excreta are stored. The mixture is duly deposited in tanks and other localities having depressions, in proximity to the dwellings of human beings. Having regard to the condition of the sub-soil water of this town, irrespective of other generally acknowledged facts as to "made-soil," the process cannot be said to be otherwise than highly dangerous to human life. In this respect Madras has been left far behind in sanitary advance by mofussil municipalities. I am, however, glad to be able to report that I believe this is the last year when Madras will thus add to the already long list of causes of preventible mortality within its limits. Government has placed at disposal a grant of Rs. 3,50,000 for purchase of conservancy plant, and for the erection of incinerators.

Under the private scavengering system in municipalities, there has been a considerable increase during the year—a total of 38,310 houses being conserved under this method against 35,252 in 1894. These increases occurred chiefly in Palamcottah, Guntúr, Cocanada, Vellore, Periyakulam, Mayávaram and Dindigul.

The allotment for sanitary purposes made by municipalities during the year amounted to Rs. 16,23,540. The amount devoted to sanitation varies with the individual municipalities. Thus, omitting towns wherein special works of a costly nature were in progress, the allotment varied from 77·5 per cent. in the case of Vizagapatam to 18·4 per cent. in the case of Anantapur. Certain Municipal Councils also failed to utilise a reasonable proportion of the allotment within the calendar year.

	Rs.	Rs.		Rs.	Rs.	
For conservancy - - -	4,95,210	4,65,506	93·8	5,23,901	3,69,982	70·6
For improvement of village or town sites.	2,59,556	2,29,844	88·5	2,45,577	1,58,139	64·3
For improvement of water supply, cleansing, repairing, and construction of tanks and wells.	5,00,326	2,72,627	54·4	7,23,917	1,40,359	19·4
For sanitary arrangements during fairs and festivals.	4,910	5,346	108·8	5,440	4,681	86·0
For construction and repair of markets and slaughter-houses.	48,888	25,708	52·6	49,493	16,947	34·2
For other sanitary objects - -	68,209	80,750	118·4	75,212	35,142	46·7
Total -	13,78,099	10,79,781	78·3	16,23,540	7,25,250	44·6

The above table shows a considerable but still not satisfactory increase of attention to the question of conservancy, or, in other words, to the cleanliness of town sites, in that additional latrines, conservancy plant and staff have been provided during the year. In the matter of latrines those erected are much superior to those hitherto employed, as all sanitary works costing over Rs. 200 have to run the gauntlet of the criticism of the Sanitary Board.

There are very few municipalities where it can be said that the storing or treatment of night-soil and rubbish after collection has any approach to exactitude or ordinary care. The night-soil and rubbish depôts are usually "out of sight and out of mind" of the caste members of municpal bodies, and, in certain of them, it can have been but rarely that those responsible have made visits to these places to ascertain in what manner arrangements are conducted. Further, even if they did, they have had no one available who could interpret intelligently any orders on the subject until recently when the municipalities have had at disposal certificated sanitary inspectors. It is hoped that when these men are employed more freely, they will be given by the Councils every opportunity of attempting to prove by object lessons the advantage of the use of night-soil in its various prepared forms as manure. Mr. Gooch, Chairman, Anakapalle, has specially applied to this office to obtain a certificated sanitary inspector, so that this matter may be put on a correct footing. In Cocanada also a special municipal garden has been opened for the purpose of cropping over night-soil. Negapatam reports securing excellent crops of jowari and raggi over night-soil trenches.

Twelve months is in certain respects a considerable period of time for attainment of progress, but when confronted with the various difficulties that are to be encountered in introducing reform, it seems often short enough. At least this is the case as regards sewage farming. In every town inspected where facilities for sewage farming exist, the necessity has been duly impressed upon the Council, but actual progress is decidedly slow. Nevertheless, the record of the year's work is not quite bare. In reference to my remarks in the report of 1893 on sewage farming, both Tanjore and Madras were called upon by Government to attempt improvement of methods employed. In the case of Tanjore, plans and estimates are now under discussion by the Sanitary Board, and it is hoped that before the end of the current year this place will possess a model sewage farm.

In the town of Madras certain of the more glaring defects, as to which I alluded in the matter of conduct of sewage farming, were rectified during the year. Thus one of the lifting stations serving the Kistnampet farm, and which each Sunday used to cease work, and allow the crude sewage to pass into the Cochrane canal, was abolished, the sewage being carried on to the farm direct by an alteration of the sewage pipe line. Still, however, this farm fails to deal with sewage for a period varying from a few hours to some days subsequent to rainfall sufficient to have caused soakage of the ground. During this period, as the cultivators find that moisture suffices for their purposes, sewage is no longer placed upon the soil of the farm; backing up of the sewage then occurs in the sewers, and relief is afforded by discharge into the Junction Canal, whence the sewage reaches the Cooum. In the DeMellow's farm, a single downpour of rain is sufficient at times to render the soil unfit for receipt of sewage till the lapse of even three days. Throughout this time, the sewage backs up in the sewer and discharges behind inhabited houses, where during part of 1895 it collected in stagnant pools that were diminished by soakage in the soil and evaporation, or found its way to a neighbouring tank. These conditions were, however, undergoing much amelioration at the hands of the Municipality during the year. It remains to be seen whether this will materially alter the insanitary arrangement hitherto pursued at DeMellow's farm of relieving the accumulation of sewage by pumping it untreated direct into the surrounding ditch, whence it passes by a tank to Cochrane canal, and thus to the Cooum, which passes through the heart of the city, and is a stagnant cesspool. Into the Cooum also is allowed to pass direct the crude sewage of the minor farms on its banks during the period of saturation of the soil. It is obvious that under-draining of plots, where this measure is applicable, or the use of sewage filters or a combination of both methods should be pursued, so as to receive sewage whilst the ground is suffering from soakage by rainfall, and is for this or other reason temporarily in an unfit condition for receipt of more moisture, and even the sewage diluted by rainfall should be treated before discharge up to a reasonable extent. With this view of matters, Government agreed in G.O., No. 818 M., dated 10th May 1895, Local and Municipal. As the question of sewerage of the town is now before the Municipal Commission, it is presumed that these and other obvious defects of otherwise well-conducted sewage farming will be duly remedied.

In the proposed scheme for sub-soil drainage and sewerage in the town of Cuddapah, the Sanitary Board suggests the use of a correctly underdrained sewage farm. This will form part of the Sanitary Works programme for 1896–97. Vizianagram during the year submitted proposals for sewage farming, but my inspection of the site showed that it would be unsuitable, owing to its being water-logged by neighbouring rice cultivation. Action, however, is being duly taken by the municipality for a new site, and I trust by next year this town may be added to the slender list. Vizagapatam has provided in this year's budget a sum of money for opening a sewage farm. Erode reports that it has commenced sewage farming on a small scale during the year.

In the matter of advance in sewage farming it has to be held in mind that as the majority of the towns have no complete drainage systems, much cannot be expected for some time to come, beyond the use of sewage on small plots by broad irrigation. I believe, however, that there exists a large opening for the purifiation of sewage by filtration. It often occurs that the sewage of two or three streets is brought by the imperfect drains at disposal to a point where soakage is permitted in great pools where land is not available, or direct pollution of streams and tanks occurs. Thus at Vizianagram, I found that the huge mass of water known as the Peddadcheruvu, which for years on end has been a constant source of nuisance to the inhabitants, receives a large quantity of the total sewage of the town *untreated*. During my inspection, under my advice, the municipal council erected a temporary sewage filter having earthen banks clay-lined and charged with under-drained broken metal, gravel, and sand, which simple expedient acted efficiently. It is hoped the municipality will now similarly treat the whole of the sewage of this part of the town, pending it being possible to make the expensive intercepting sewer necessary to lead it to a sewage farm, and thus prevent pollution of the tank. In this town I also attempted the introduction of a household sewage filter, which has since been tried at Negapatam and Coimbatore and Bellary. The idea of filtering sewage at the household is, of course, not original. Dr. Poore specifically refers to this mode in his "Rural Hygiene," and Mr. Scott Moncrieff also practised it. There is, however, much scope for adaptation. Thus, in the form used here, I employed a simple iron kerosine drum having a central funnel whereby upward filtration through stones, gravel, and sand was employed. The action of this simple and inexpensive filter is very good up to 10 to 15 days. The filtrate is clear and odourless. But this provides indifferently for the essential of sewage filtration, namely, æration of the filtering media on account of these being more or less water-logged. This form would, therefore, be best combined with a second filter to receive the filtrate of the first by downward filtration, the first filter acting more as a strainer. I have recently made other forms of domestic filters allowing of forced æration by a hand bellows, and by the intermitting action of a syphon.

I consider that the adaptation of sewage filters to the requirements of native households will effect much good in those localities where no drains exist. Seeing that the filtrate is allowed to soak on the ground surface (unless it happens that vegetation is at hand) the device does not get rid of the difficulty that soakage and dampness of soil is still not prevented. Still, it is better that the threshold of a poor man's house should be soaked with a fairly pure sewage filtrate than with pools of untreated sewage, or that he should launch his sewage into the sub-soil direct by means of pervious cesspools as largely practised. In using this method for the first time, it is of course essential to see that the whole area on which crude sewage has formerly soaked near a house be correctly cleansed, and that fresh earth be placed in position. The filtration media when they require to be changed form good manure.

In the case of Vizagapatam, much of the sewage of the town is sent direct into the swamp caused by the backwater. The result is that the swamp is an abominable nuisance. Here, also, I found an admirable case for filtration of sewage before discharge. The Chairman, M.R. Ry. B. Suriyanarayana Sastri, quickly fell in with my views, and had made whilst I was there an under-drained sewage filter. He describes the results as follows:—"The amount of sewage daily dealt with is about "7,200 gallons (= 750,000 per acre); the filtrate is clear and looks like pure water. "At first a few days after the filter began to work the filtrate tasted brackish, now it "is not so."

A considerable gain in the matter of the repression of epidemic diseases was obtained during the year by the action of the Government in regard to the failure of the Municipality of Trichinopoly to take adequate precautions, in spite of advice offered as reported by me during the epidemic of cholera in that town in 1893–94.

when 1,500 persons perished. In their order on this subject, Government affirmed the responsibility of municipalities, especially in regard to prompt action upon advice offered by the local sanitary officers or by this office. This plain declaration of policy has been, I believe, instrumental in securing during 1895 a far greater display of energy in endeavouring to repress an epidemic at its commencement by municipalities than has hitherto been the case in the history of this Presidency.

Beyond the improvements effected under major works, advance in the all-important matter of improvement of water-supply has been less than could be wished, but it is far more difficult to get a municipality to act in the matter of protection of water-supply than the disposal of sewage. Sewage is a nuisance that all are glad to get rid of, and so long as the expenditure contemplated is not very great, petty schemes for its removal are readily voted for; but to persuade a council that water they have used day by day for many years on end—albeit that their less lucky contemporaries who also used it died prematurely—is unfit for use is not so easy a task. There is still a decided tendency to regard the dipping of hands, feet, and chatties into drinking-water tanks as a matter of little consequence, in virtue of the self-purifying powers of water. Even where the question of the introduction of a public water-supply is discussed, there are always to be found members who will strongly oppose any other mode than the bringing of water into the usual type of open tanks within the town. Nevertheless, under expenditure for improvement of water-supply, there has been an increase this year over the past that bespeaks a certain amount of energy in this matter. I conceive that a want of familiarity with apparatus and methods usually employed to fulfil sanitary ends is at the bottom of this want of appreciation. This can only be got over effectually by the opening of a public museum of hygiene, that should serve to illustrate fully the practical side of municipal sanitation.

The Sanitary Aspects of major Works discussed by the Sanitary Board during 1895.

Ootacamund.—As a result of a sanitary survey, aided by analyses conducted by the Chemical Examiner of samples taken at the different sources of supply at various parts of the storage reservoir, and at definite depths in them, I reported in my inspection notes embodied in G.O., No. 648 M., dated 23rd May 1894, that there could exist no doubt that the Marlimund reservoir was unfit for the purpose of storage, its bed—as subsequently proved by samples removed from the bottom by the Acting Sanitary Engineer Mr. Ellis—being formed by a mass of vegetable matter, which consisted of but partly transformed peat subject to ready decomposition. Within the catchment area is a coffee estate, which contributes impurities of animal origin.

It was therefore advised that the existing reservoir be abandoned and a new storage reservoir be built, that catchment areas where unusual masses of vegetable matter undergoing but slow change in the depths of dark and thickly-wooded jungle should be abandoned, in favour of clean grass land which was available, and that certain springs be collected to compensate for ground thus lost. The whole question was fully discussed, after inspection of the reservoir and catchment area by the full Board (Colonel Pennycuick, C.S.I., Chief Engineer to Government, President, Mr. Jones, Sanitary Engineer, and myself). It being found impossible to supply a few houses without resort to the Marlimund reservoir, I advised the use of Anderson's revolvers previous to subjection of the water to ordinary sand filtration before distribution. The general principles laid down were accepted by the Sanitary Board, its conclusion being aided by a very careful and detailed report on the subject by Mr. Ellis, Acting Sanitary Engineer. There being, however, much engineering work to be undertaken before a complete scheme could be formulated, the Sanitary Board advised the entertainment of an engineer who could devote his time to its special investigation.

In the above inspection notes I drew attention also to the defective state of the "intercepting sewer" at Ootacamund, showing that it was incapable of fulfilling its supposed functions. This matter was also discussed by the Sanitary Board, and its failure was ascribed to imperfect laying by the local engineer. In connection with this matter, the question of sewage farming for Ootacamund was discussed.

I took the opportunity at a special meeting of the Municipal Council of Ootacamund to urge the necessity for their taking up the question of the sewerage of the chief part of the town at the time of altering the intercepting sewer, so as to derive its full advantages.

The reclamation of the upper lake of Ootacamund and the improvement of the ground already reclaimed by sub-soil drainage were also questions discussed by

the Sanitary Board. Govefnment was advised that both works were sanitarily necessary.

Salem.—This is one of the towns that not only suffers from impure water, but also from scarcity of supply. Mr. Ellis, Acting Sanitary Engineer, having proposed a sub-soil water scheme, the Collector of the district in the interest of the municipality brought the matter before the Sanitary Board. The Sanitary Board advised the tapping of the sub-soil stream at its probable outlet—the river. But a sanitary survey by me showed that this would be undesirable, and I advised the tapping of the sub-soil near the Namem Hill, and pointed to possible additional sources in certain springs and surface water proceeding from the back of the Gurumallais. This matter is under investigation.

Cuddapah.—My inspection notes, No. 182, dated 7th February 1895, discussed fully the causes of excessive prevalence of malaria in the town of Cuddapah, in reference to obstructed sub-soil and surface water flow, and saturation of the sub-soil with sewage from pervious cesspools. I urged a pipe sewerage system accompanied by a complete sub-soil drainage system, and the filtration of the existing public water-supply. With the views expressed, the Sanitary Board concurred.

Coonoor.—In my inspection notes (G.O., No. 800 M., dated 6th May 1895) I urged that the source of supply selected by the Sanitary Engineer should not be accepted by the Municipal Council without further investigation as to other possible sources; and, especially, that it should not, even if chosen, be used without the precaution of using filtration, and cutting off certain undesirable portions of the catchment area. I suggested that a source partly discussed by the Sanitary Engineer might be feasible if certain adaptations were made, but which I had not had time to investigate. Subsequent inspection of this source by me, however, showed that it was not sanitarily preferable to that already selected by the Sanitary Engineer. We, therefore, met at Coonoor and exchanged views, with the result of advising an investigation of a new source that seemed to us more likely to yield an unexceptionable supply.

Bezwada.—In my inspection notes (G.O., No. 521 M., dated 23rd April 1894) I warned against the selection of a site for water supply of that town on the ground that, though wells were to be sunk in a reclaimed part of the river-bed, their position was such that a draw upon the sub-soil water of this undrained town was possible. This matter was still under discussion at the end of the year by the Sanitary Board.

Gudiyáttam.—In my inspection notes (G.O., No. 1237 M., dated 1st August 1895) I pointed to Gudiyáttam, though small in population, as a town where, on account of frequent visitation of cholera, it was most desirable a protected water-supply should be obtained. In default of it being possible for so small a town to bear the charges of a sufficiently complete scheme, it was suggested that a cheap system of distribution should be employed, looking to infiltration galleries in the river sub-stream as a source. The Assistant Sanitary Engineer thereupon presented a scheme which usefully modified the rough proposals made by me. The scheme was, at the end of the year, still under discussion by the Sanitary Board.

Calicut water supply.—In my inspection notes (G.O., No. 513 M., dated 23rd April 1894) I objected to the use of the Mananchera tank as a source of water supply that had been selected by the Sanitary Engineer's department, until further investigation had been undertaken. I advised that the sub-soil water in the neighbourhood of Calicut should be explored, with the object of obtaining a site less open to objection as to purity of the area drained. If, however, the Mananchera tank were used, I showed that the chances were it would be found that it possessed not only a supply from the sub-soil, but that probably during excavation the impermeable stratum supporting the sub-soil water had been penetrated, so that a subterranean source had been tapped, which contributed to the total bulk. It was then pointed out that, whilst the sub-soil water in this particular position was objectionable, it might be possible to utilize the tank or its neighbourhood, provided an iron cylinder were sunk, that should, whilst giving egress to the subterranean flow, completely cut off that from the sub-soil. The Chairman of the Municipality has since forwarded to Government proposals that, with the exception of suggesting a concrete ring in lieu of the iron cylinder, coincide with the above; but has, at the same time, apparently from failure to consult my notes at time of his writing, attributed to me views that were not expressed by me. In the meantime, Mr. Ellis, Acting Sanitary Engineer, had proposed the use of certain springs in the neighbourhood that, in the event of the theory as to a subterranean source not being verified, offers an excellent alternative. The matter was before the Sanitary Board at the end of the year.

Works completed during the Year.

Only the following two works were completed and opened for public use during the year 1895:—

Adóni waterworks (population 28,305).—This is a surface water scheme commenced in November 1893. The storage tank is an old one, and was formerly used for irrigation purposes. Much of the catchment was originally rice land. This the Municipal Council has duly bought up. The remaining catchment area is not without objection—being largely cultivated land. The Municipal Council has been advised to acquire the rights over the valley by purchase as early as possible. The town is supplied by gravitation from filtered water reservoirs. The three filters measure 50′ × 40′ each, which, with two in action and one out, will permit of filtration of the 230,000 gallons required at a rate a little over Koch's limits. The water enters the filter-beds at single points on one side instead of being distributed as evenly as possible. The filtering head is controlled by telescopic pipes; but the man in charge has to trust to the use of a rough stick and tape, as no gauges are provided. I have urged the Sanitary Board, without avail, to render the filtering speed of filter-beds as largely under control of automatic arrangements as possible, in view of the poorly-educated class of men likely to be entertained in municipalities for charge of these works. No arrangement exists for filling the filter-beds on starting from below with filtered water. The only place available for drying the washed sand of the filters is a verandah of a house. The collection of sand for the filter-bed was during the year from undesirable localities. The filtered water reservoirs are incompletely dark, and inefficiently protected from heat and dust by a corrugated iron roof. These are all readily removable sanitary faults.

The Tanjore waterworks (population 54,390).—The water is obtained by pumping from an infiltration bed in the river Venár. On the banks within a hundred yards of the filter-bed is a chatram in which a cholera patient died in 1894. I have advised the municipality to abolish this; otherwise the site is not objectionable. I found on inspection that the engines ceased work on Sunday, so that on each seventh day the people were dependent upon their old contaminated sources, and aspiration through empty pipes of undesirable matters was possible. I have advised the municipality against this. The purity of the water in the case of this town will have to be watched carefully, as the rate at which the water from the surface flow, when the river is not dry, passes to the collecting well through the filter-bed, must vary considerably with the rate of pumping. The Sanitary Engineer informs me that he intends suggesting the making of a service reservoir that will receive all surplus water pumped, and will thus keep the pipes full and prevent the danger of aspiration during intermittence. This will form an important sanitary addition to this work.

Sanitary Results of Works completed.

1. Madras.—(1.) The public water-supply having been introduced in the various divisions of the Madras town at different periods, it is necessary to treat the town not as a whole, but with regard to this fact. Black Town being the locality which is supplied both with a sewerage scheme and public water-supply, it ought to be possible to show a marked improvement in the general health of the population. But no permanent material change for the better can be demonstrated. This disappointing result can only be ascribed to the incomplete manner in which the sanitary works have been carried out. Thus, the Black Town sewerage scheme is on the "open system." This system has its sanitary disadvantages, but still the open *versus* the closed sewerage system for native towns is a question that is still subject to much discussion, and much can be said on both sides of the matter. Personally, I do not like the open method otherwise than when unavoidable in small villages, but there can be no reason why it should not have secured in Madras Black Town obvious sanitary good, had the details as to house connections been correctly completed. The arrangements for a system of night-soil conservancy specially suited for the "open system" of sewage removal have never been more than partially adopted. Again, as to water-supply, notwithstanding the existence of the public water-supply, householders in Black Town, as throughout Madras, use shallow well water, that is, water from the sub-soil that is saturated with filth, as testified to by repeated borings disclosing "made-soil" in many localities. The "old main drain," which is an ancient structure, fit at the best to run off surplus rainfall, I have found by personal inspection to be freely pervious. This old drain runs at right angles to the sub-soil waterflow of Black Town. Yet this daily receives a large amount of sewage that the modern sewer No. 1 fails to discharge,

and is retained there until pumped from it. Can it be imagined that under these conditions of known filthy sub-soil (so filthy that it has been described as of the colour of "tin-sand") that shallow well water is a fit fluid to use even for the washing of domestic vessels, irrespective of its use at times for drinking purposes? It seems to me clearly the duty of the municipality of Madras, if they wish to see results secured by the past expenditure on water-supply and sewerage, as a first step, to see that these shallow wells are shut. Power that would enable them to secure this end has been conferred in the Revised Act, No. II of 1892. The excuse that the private latrines and drains would suffer if the wells were closed seems to me an unhappy way of regarding so urgent a sanitary matter. The amount expressed in gallons actually used per head from the pipe supply in 1894 in the divisions where water has been introduced was 12·6 of the estimated population. This is doubtless scanty; but it must be remembered, though in the outlying parts of the town the supply is limited owing to defective pressure, that in the populous areas this is not so markedly the case, and that more could be drawn off here, if the people had not the inducement of a supply from wells nearer at hand than the public stand-posts.

(2.) I have in special reports shown how open to contamination the Madras system is by reason of intermission and defective pressure where leaky pipes in the filthy sub-soil and fittings are concerned. To this must be added further the fact that the water-supply is received from a doubtful collecting area, flows in an open channel, and is not subjected to filtration before delivery. Until the water-supply of Madras is at least guarded by filtration, and, if feasible, by a covered conduit bringing water from a catchment protected from defilement, and is delivered under reasonable pressure, it is not likely the town will get the full benefit of the expenditure undergone for a water-supply; and as long as the municipality neglects to shut shallow wells used by the people, it is impossible to hope it will secure any marked benefit even if the public supply were itself not open to suspicion.

(3.) The extension of a sewerage system to parts other than Black Town is still the subject of discussion by the municipality as it has been during the last 30 years, notwithstanding the advantage of having had schemes prepared by three European experts at intervals in that period. It is believed that a decision is likely this year.

(4.) In the meantime, a scheme for flushing the river Cooum—which is the recipient of a large proportion of the total sewage and is land-locked—by aid of a canal communicating with the sea near the harbour has received the assent of Government.

II. Madura.—Here a decrease of the death-rate has occurred, since the public water-supply had been opened. But I think it would be premature to ascribe this to the influence of this sanitary work, as the people have had to depend very largely upon their former sources of supply; because the amount of water yielded by the infiltration beds was less than had been hoped by the Sanitary Engineer until, by good fortune, at the end of the year, the completion of the Periyár Works brought surplus water into the river Vaigai. Indeed, not only would this fact militate against drawing conclusions, but I consider the reduced death-rate simply implies increased carelessness in registration on the part of the Municipal Council, as both the birth and death rates have simultaneously decreased without good cause.

III. Coonoor.—Here a general improvement in the death-rate seems to have occurred since the introduction of the sewerage system, although this conclusion must be guarded by the fact that if the statistics were formerly trustworthy, Coonoor has yet not reached the condition of health found in 1886. The chances are, however, in favour of the change being due to the better drainage of the place. Yet a sanitary inspection of the works brings the conviction that much remains to be done. Not only is a considerable portion of the town not attended to, but the arrangements within the houses for connecting with the "open drains" of the system are such as to ensure that a large quantity of the total sewage never leaves private premises. No action in this matter seems to have been taken by the Municipal Council during the year. The encouraging results as to the death-rate ought to induce them to render the system sanitarily complete, by attention to the house connections and flushing arrangements.

IV. Ádóni and Tanjore.—Ádóni and Tanjore water-supplies having been opened only during the year, no conclusion can be drawn; but as in both instances the people still are using largely the old supplies, the full influence for good cannot be expected. In Ádóni the works are appreciated by the mass of the people; but, in Tanjore, there is

much conservatism exhibited even by the highly educated, and the most filthy sources of water supply are still resorted to. On the latter matter, the Sanitary Board made special representations during the year.

V. Kumbakónam.—As remarked last year, the drainage scheme here is merely for the removal of surplus surface water, and, although the unlined trenches dug for this purpose may have some influence in their vicinity in lowering the sub-soil water, it cannot be hoped that any marked improvement in the general health of the town will occur from this work. The existing water-supplies and general sanitary state of this town are unusually evil.

VI. Cuddapah.—Here there would seem to have resulted some improvement on the death-rate following the introduction of a purer water-supply. This is shown both by a rise of the birth-rate and a fall of the death-rate. In view of the theory of propagation of malaria by water, and the late hypothesis of Dr. Manson (supported by the late observations of Surgeon-Major Ross of the Indian Medical Service), there is reason to believe that, in the protected water-supply derived from a clean source, much good has been effected; so that with the further improvements contemplated as to sewerage, sub-soil drainage, and filtration of the existing water-supply, there be yet hopes of making Cuddapah healthy.

District Boards.

No change in the method of administration of district boards was effected; their position being regulated by Act No. V of 1884. This Act is practically devoid of any power by which sanitary efforts can be enforced. Hence, although these boards collect funds and spend a certain amount in the cause of sanitation, they can do but little in enforcing precautions that should form the corollary of their position. The Act has been for some time under the consideration of Government, and now that the revision of the District Municipalities Act is an accomplished fact, it is hoped this will in due order be taken up. Until this be accomplished, very little can really be done in rural areas. Indeed, it may be said that, excluding the united population of the 57 municipalities, the remaining population of the Presidency, viz., 33,499,932 is subject to little sanitary control beyond what can be effected by the aid of "persuasion" exercised by the revenue authorities. For example, granted a union be duly embodied, and members of the panchayet gravely meet in consultation as to the sanitary reform of the village, one of their first orders would naturally be to give notice to persons having buildings and lands in an unwholesome state to effect cleansing, but experience would show them that an owner may allow insanitary conditions to exist safely for 30 days subsequent to receipt of notice, when the Taluk Board may cleanse the place for him *at their own expense.* Similarly, as to protection of water-supplies, the position is not much better; as, whilst if a stream is private property, the Board can enforce certain attention to the preservation of its purity, this cannot be done where the stream is public. Yet, a very large proportion of the total population looks to streams for their water-supplies, whilst the conveyance of cholera by this means from village to village is open to no doubt.

The total sum devoted to sanitary purposes (Rs. 696,498) exceeded that of the previous year by Rs. 41,093. As usual, the proportion to their incomes given by district boards varied within considerable limits; for example, whilst Gódávari, and Tinnevelly gave 15·3 per cent. of their incomes, South Canara, Malabar and Nilgiris afforded but 3·5, 2·6 and 1·9 per cent. respectively. Again, expenditure was subject to equally varying results. Thus, the districts of Gódávari, Kistna, Salem and Madura expended but 31·5, 42·4, 42·5 and 47·9 per cent. respectively of the allotment, and although I somewhat encroach upon history, I have ascertained that by the end of the official year 1895–96 the district of Tanjore had spent but 52 per cent., Kistna 48, and Coimbatore but 47 per cent. under the very important item of improvement of water-supply. Nevertheless, as far as my information goes at date of writing this report, there has been, on the whole, a slight improvement in attention on the part of district boards to the necessity of spending the allotments made.

In the case of water-supply the total allotment amounted to Rs. 1,48,318. Very little of this sum, however, represents new works of a permanent nature. A large portion of it disappears under "staff" maintained for guarding the purity of tanks. Such works as were fulfilled at district board's expense were essentially petty, consisting of repairs to wells, deepening tanks and the like. No district board in this Presidency has yet determined upon any scheme of water-supply that would secure pure water for a whole town, although the average total income, excluding the

Nilgiris, amounts to Rs. 3,69,895 per district. Yet it seems to me that only by undertaking in town after town comprehensive radical sanitary improvements it can be hoped real progress in the rural towns can be effected. If district boards would systematically improve the large towns under their charge, and subsequently hand them over to unions—furnished with more sanitary and financial powers than at present—much more evident results would follow than can be expected by dividing the total available funds into petty allotments of Rs. 150 for this village and Rs. 30 for that, and so on. If permanent improvement were made the result would be, that in lieu of the sanitary safety of water sources being in the hands of human beings, having varying standards of conscience, it would be in the safe keeping of mechanical means. Thus, taking the ordinary case of two watchmen in charge of a village tank at Rs. 6 each, there is expended the equivalent of interest on Rs. 3,200 at $4\frac{1}{2}$ per cent. Mechanical improvements would, in many cases, relieve local authorities of the perennial charge for watchmen. If they cannot meet the cost of special works at once, it would seem but reasonable that, instead of indefinitely postponing efforts, they should seek the sanction of Government to borrow funds.

The number of unions and villages concerned increased by 11 during the year. Government has in various orders to local boards impressed upon them the necessity of seeing that the question of disposal of excreta takes precedence of mere rubbish disposal. Unfortunately, sweepers—persons who will collect rubbish—are obtainable at far cheaper rates than scavengers—those who will collect night-soil. Indeed, in some districts, the prime difficulty as to night-soil disposal is the obtaining of this class of labour. It is time, therefore, that where this is the case organized efforts should be made to attain this end. This can readily be accomplished by local authorities importing these people from more favoured localities, and guaranteeing them certain privileges as to huts and lands. In short, efforts should be directed towards founding colonies of these people. This seems a small matter to dilate upon, but the gradual extinction of the scavenger before the advance of education in this country threatens to be a matter quicker of accomplishment than the abolition of caste, whilst, with every attempt at sanitary advance, increased demands upon the manual labour available will present difficulties that could eventually only be overcome by the application of expensive mechanical measures. Of course, the founding of colonies cannot stay the influences of the advance of education in lifting the "toty" beyond the sphere of his present conception of a suitable professional career; but there would result a better distribution of available labour, and numerous low-caste families that would not, in the immediate vicinity of their native places undertake this menial work, would not hesitate to do so when settled elsewhere.

Arrangements as to fairs and festivals, I consider, have, during the year, undergone improvement. There is more tendency by local authorities to work out what is required in each case with the aid of the district sanitary officer, who is now, as well as this office, supplied with an intimation a fortnight before the occurrence of each festival. It is premature till experience in future years is obtained to draw definite conclusions, but, so far, it would appear that the timely taking of special precautions at both Tirupati and Tiruvannámalai (the two great festivals that have hitherto contributed to cholera spread in this Presidency) was of considerable utility. Cholera had occurred at Tiruvannámalai in the month preceding the festival, and one imported case occurred there on the last day. In Tirupati, on the opening of the festival, cholera appeared at one of the pilgrim halting places within three miles of the town, and, again, a further imported case took place during the festival. No spread from these centres occurred, owing to the sanitary staff being sufficiently strong and intelligently alert to secure quick and efficient segregation of the affected persons and correct disposal of infective matter. Exceptionally large amounts were spent at these festivals; the new class of certificated sanitary inspectors were employed for supervision of fairly complete menial staffs, and water-supplies were protected from defilement by mechanical means as far as possible—doubtful sources other than sacred tanks being closed. In both localities the district authorities threw themselves into the work involved by a heavy list of recommendations by me with the greatest cordiality. Water drunk hot is a diffusible stimulant, of the advantages of which the native is well aware. Hence, there was found no difficulty in getting pilgrims to avail themselves of the free distribution of water that had been boiled by caste natives, and was still hot, during the seven miles trudge up the hill at Tirupati. But the festivals at these places were, I think, worthy of special notice in recognition of the accomplishment of what has hitherto been regarded as an impossibility. No direct washing of clothing in any tank was permitted. Kerosine-oil tins were provided for drawing water, which were then used on a specially prepared drained spot, where were

placed the usual dhobie stones. In the case of the holy tanks, where bathing is requisite as a part of the religious ceremonies, it was held that washing of the clothing was no part of the ceremony, and that it was but in accordance with the tenets of Hinduism and common cleanliness that before descending into a holy tank the pilgrim should be able to prove that he had already undergone a grade of *bodily* purification. Hence, it was insisted that no pilgrim should descend into a tank for the ceremony of bathing until he had washed himself and clothing outside the tank. At Tiruvannámalai special barricades were made for this purpose, and by carefully controlling traffic the desired end was accomplished. In Tirupati this arrangement was not effected with the full completeness desirable, but at Tiruvannámalai it was carried out sufficiently well to ensure that on the last day of the festival the Ayarkolam, which in former years was a filthy mass of water, was perfectly clear. Of course, this arrangement did not prevent danger, but it at least minimized the chances.

In connection with the conduct of the Tiruvannámalai festival during 1894, I had occasion to invite the attention of Government by a special report to the very indifferent measures taken for the comfort and sanitary safety of pilgrims during transport by rail. In G.O., No. 590 R, dated 20th September 1895, certain regulations were thereupon required of the railway company by Government, and I am glad to be able to state from personal inspection that much improvement upon the former condition of affairs was effected.

In 1890, when Acting Sanitary Commissioner, I drew attention to the fitness of the Jewish method of conservancy described in Deuteronomy, chapter xxiii., verses 12 and 13 for use at festivals. It was not, however, until the Tiruvannámalai festival of 1895 that I had personally an opportunity of seeing it worked on a large scale. It is certainly the most expeditious, cleanly, economical, and sanitarily sound method yet used, and is much appreciated by natives. It being hopeless to expect the pilgrim to take the initiative in this matter—as was expected of the Jew—it was arranged that places at the outskirts likely to be resorted to were guarded by policemen. These restricted the pilgrims to a certain portion of a field marked off with flags. Within this area were the requisite holes scooped at regular intervals, each marked by a small piece of up-right bamboo, and strip of coloured rag. A scavenger was kept in constant attendance, and the moment a hole was utilized this man proceeded to the spot, removed the bamboo which marked the site, and by a motion of his foot filled in the hole with the dry earth which had been excavated and placed at the side. I describe this simple mode in detail, not only because of its special suitability for natives, but because it is possible to get men to cover the holes who are not scavengers, as nothing defiling is touched; and where every one of this class at a festival is of the greatest value on account of the difficulty of obtaining them, any method that can be worked without their aid is of practical utility.

It having been found that where local authorities employ conservancy staffs, no account was forthcoming as to the manner of *ultimate* disposal of night-soil and rubbish, a special circular was issued to District Medical and Sanitary Officers, inviting them to note in each report not only as to the mode of temporary deposit, but as to what uses, if any, the materials were placed to. The result has been to show that in many unions these are simply thrown on waste places pell-mell, and that in others no fixed depôts exist. These are points that have been referred to local authorities as cases were brought to light, with the result of securing promises of improved methods, more especially directed to ultimate economical disposal as manure. Reports received from Collectors of districts in the matter of attempting to secure the use of night-soil as manure by the influence of tahsildars upon villagers, go to show that very little actual progress has been effected; all that can be done is to keep the matter constantly in view, and to preach its advantages in and out of season.

General Remarks and Personal Proceedings.

During the year a total of 9,125 miles by rail and road was travelled by myself, and 5,561 by the Acting Inspector of Vaccination and Deputy Sanitary Commissioner, Surgeon-Major C. Mallins, D.P.H. Twenty-eight municipalities were inspected, and full reports on the sanitary condition of each were submitted to Government. Twenty-five unions and 62 villages were also inspected.

Whilst the number of municipalities inspected during the year is less than formerly, the attention given to festival resorts and rural tracts has been greater. This is due to my representation to Government that the system by which, in the course of the year, each municipality had to be inspected by either myself or deputy, was of much less

utility than might be anticipated. A calculation of the time at disposal when allowing for a reasonable rate of travelling, and for fulfilment of other special inspections required by Government showed that such inspections could not be otherwise than superficial, and left no time for entering into the numerous details involved in the sanitation of the larger towns with the attention requisite. Regarded even from the light of physical endurance, the task of inspecting on foot all parts of towns having the large areas found in this presidency could not be regarded as otherwise than demanding considerable time. Further, whilst more time and attention were requisite from me in the matter of repression of epidemics, and the inspection of, and suggestions for, the safe conduct of festivals, the state of the organization of the vaccination department demanded that more time should be devoted by the Inspector of Vaccination to verification of results, which experience daily taught was very requisite. Had it been found that the advance made in municipalities was in any way proportionate to the rapidity and multitude of the inspections made of them, this consumption of time would have been justified; but I found that what with the period required for submission of the report, its discussion by the Municipal Council and orders thereon by Government, and consideration of plans and estimates by the Sanitary Board, there remained but little time before the termination of a year for improvements to be really effected. Hence, to visit a municipality two years in succession, was to find that practically nothing had been done in the interval since last report. Government agreed with this view of matters, and directed inspection of municipalities to be, as a rule, conducted every second year, leaving it to my discretion to visit others oftener where this course would seem requisite (G.O., No. 1280 M., dated 6th August 1895).

To secure that there should be no forgetfulness of the fact that certain recommendations had been made, and that the Councils had duly pledged themselves to make reforms, I suggested that District Medical and Sanitary Officers should be desired, on receipt of copies of the inspection notes of this office, to take cognizance of the improvements that had been agreed to by the Municipal Council concerned and report the fact to me, should there seem to be unreasonable delay in effecting these (G.O., No. 1618 M., Mis., dated 9th October 1895, Local and Municipal).

It having been found by me that recommendations made to municipalities frequently were not fully understood, it was suggested that they should be required to hold meetings before my departure after fulfilment of inspection duty, with the object of enabling all recommendations to be discussed fully. This view was accepted by Government in G.O., No. 1280 M., dated 6th August 1895. The result of this interchange of views has, I think, during the year been advantageous, both in the case of the municipalities concerned and myself, in that I can explain fully what is aimed at, and am able to judge as to difficulties that may have to be overcome.

I was required by Government to investigate the connection between the burial of Moplahs dead of cholera, and an outbreak of that disease that had occurred in Palghat, and to select new burial-grounds. In Calicut, the Moplahs had for many years effected burials under highly insanitary conditions, the sites being close to houses, the inhabitants of which derived their supply from shallow well water. In 1890, the Moplahs living under these conditions died of cholera to the extent of 3·5 per cent., whilst Hindus living in the same town died to the extent of ·3 per cent. of their respective populations. The then District Sanitary Officer, Surgeon-Lieutenant-Colonel Beech, made strong representations on the point, with the result that the often-agitated question of Moplah burial was revived. The municipality was then directed by Government to select sites for new burial-grounds, in consultation with the leading Moplahs. On these sites so chosen, I duly reported. Special reports were also required by Government as to the conditions of burial and cremation near the river at Nellore and at Salem, respectively. Orders were also received for the inspection of 29 Muhammadan burial-grounds within the town of Madras. The latter work occupied a considerable time.

In accordance with G.O., No. 1551 W., dated 10th June 1893, Public Works, requiring the Sanitary Commissioner of a province to sit on committees determining the boundaries of cantonments, I inspected and reported to the military authorities on the proposed boundaries of the Wellington Cantonment.

In the beginning of the year, a severe epidemic occurred within the Lunatic Asylum in Madras. With the Surgeon-General with the Government of Madras, I made an inspection of the asylum, when evidence was forthcoming which seemed to show us that a latrine had been contaminated by a case that was not recognised at first as cholera by the then medical officer in charge; that the brooms used for this latrine and

for the washing of floors in sleeping cells were not readily distinguishable, and that this labour was conducted by the same men; that the pails used for drinking water and for flushing the floors were not readily distinguishable, and may, therefore, have been used indiscriminately, and consequently may, and probably were, plunged into a bathing cistern; that this bathing cistern being open, it could not be said that lunatics did not have access to it as drinking water—the probability being that this was the case. Indirect contamination of this water with cholera excreta conveyed by brooms, hands, and pails, seemed, therefore, probable, and it was accordingly suspected by us that the open cistern had been the medium of spread in the first cases. The suspected water was sent to Mr. Hankin for examination, who stated that it contained bacilli "indistinguishable from cholera." In the epidemic of cholera in the Trichinopoly Jail in 1893, the conditions similarly pointed to contamination of water kept in open cisterns for bathing purposes. In view of the strong opinions held by Indians as to the self-purification of water, it is obviously an error to maintain these in any public institution.

Two central and six district jails were inspected by myself, and two central and three district jails by my deputy. Several sub-jails were also inspected. The results of inspection were forwarded to the Inspector-General of Prisons.

Under orders from Government, the Hill Jail of Párvatípuram was inspected, with reference to the continued prevalence there of dysentery. A lengthy report on the subject was submitted to Government.

The question of effecting radical improvement of the arrangements for water-supply in jails, which was pressed upon Government by me in November 1894, was again brought to its notice in 1895, with the result that orders were issued requiring the Inspector-General of Prisons to forward a list of supplies that demanded attention.

With the Surgeon-General with the Government of Madras certain aspects of the food-supply of sub-jails were considered; with the Inspector-General of Prisons the matter of treatment of water in sub-jails, and the provision of cheap, yet not easily contaminated, surfaces for receipt of cooked food supplies was discussed; special measures were advised as to the too prolonged use of earthen lotahs for drinking purposes.

Tirupati was visited twice during the year; once with reference to a special request of the municipality inviting my opinion regarding a proposed tank for religious ceremonies, and, secondly, for inspection during the festival. A careful inspection of both Upper and Lower Tirupati in the previous year enabled me to detail the measures I considered requisite. In the case of Tiruvannámalai, a full report founded on personal inspection of the locality was drawn up previous to the festival, for guidance of the local authorities concerned. I also inspected this place during actual progress of the festival. Vélánganni and Little Mount were also specially visited during progress of the respective festivals. Tirukkazhikkunrum and Tirukachur (both places where festivals take place) were inspected.

Having regard to the orders issued by Government as to improved arrangements for pilgrim traffic by rail (G.O., No. 590 R., dated 20th September 1895) in connection with my representations as to the Tiruvannámalai festival, the Agent of the South Indian Railway, Captain Shelley, R.E., suggested a conference with me, accompanied by the officers responsible for traffic and medical arrangements on the South Indian Railway. It was agreed to invite Mr. Castle-Stuart Stuart, Collector of South Arcot, as a representative revenue officer known to take an interest in sanitary advance, to aid the committee with his advice as to district organization. It was resolved to forward recommendations to Government; but, when finally circulating the Proceedings of the Committee, it was found that the concessions made by the railway authorities beyond what was required by the Government order were so trivial, that the whole subject required reconsideration. A further conference has been consequently suggested. In the meantime, the display of willingness on the part of the Agent to meet the sanitary requirements and the discussion of the various points involved in their various financial, administrative, and sanitary aspects, cannot fail to secure increased attention to this important subject.

Mr. Hankin's suggestion to undertake disinfection of wells with permanganate of potash was pressed upon the notice of all district medical and sanitary officers and all local authorities, by means of circulars. Special tables showing weights of permanganate required for different sizes and shapes of wells under ordinary conditions of organic purity, were also circulated for the guidance of medical subordinates. The method has been freely practised. On the whole, the opinion of district medical and

sanitary officers is that this mode is of efficacy; but this cannot be confirmed without prolonged experience, as indeed contended by Mr. Hankin.

Disinfection of wells by alum and lime was practised by me at the festival of Tirupati in 1893, with apparently good results. In view, however, of Mr. Hankin's advocacy of permanganate, I now confine the use of this method to unmanageably large water-supplies, and especially to use in bathing and washing tanks. Failing its being possible to use even this method, on account of the bulk of water in certain tanks in the Tiruvannámalai festival, I directed precipitation to be affected at nights, after withdrawal of the pilgrims within 25 feet of the edges, a method better than none—having regard to the known slowness of diffusion of impurities in quiet masses of water.

Circulars, giving hints to non-professional persons as to investigation of outbreaks of cholera, describing "make-shifts for sewage disposal in the absence of sewerage systems," in which the various temporary expedients applicable were discussed, and calling attention to the desirability of registration of births and deaths, and affording reasons why members of Municipal Councils should not treat, with the leniency hitherto exhibited, delinquents under the compulsory clauses, were circulated to local authorities. A translation of Koch's paper, advocating subsoil water for sources of supply, provided the area drained is cleanly, with special reference to his suggestion for protection of wells that seems peculiarly applicable to so-called "step-wells" in this Presidency, was also circulated for general information.

As Government has required that I shall not enter into dissertations in the annual report as to cholera causation, I have purposely avoided any theoretical discussion as to the marked decrease of cholera prevalence in this Presidency—a decrease not equalled through eight years. Holding in view, therefore, the fact brought to notice in the annual report of the Sanitary Commissioner with the Government of India for 1894 that, with the proof of connection of the cholera bacillus with cholera causation, the subject of fluctuations of epidemic prevalence cannot be considered closed, and remembering the fact that at long intervals great depressions of cholera prevalence have occurred in the history of this presidency, it would be unsafe to draw a deduction that might by next year be shown to be false, by an exacerbation. Still, I think, it would be illogical not to describe this decrease *to some extent* to the better activity on the part of all local authorities in connection with prompt repression of epidemics. In each instance of an outbreak inquiry is at once made by this office as to measures being taken, and where action on the part of local authorities seems dilatory, special representations are made. This continued "worrying" of local authorities, as this system has been graciously described to me by certain of those concerned, has, I believe, not been without its influence, in that the process having been impartially applied to every part of the Presidency has secured what was aimed at—the taking of prompt and effective measures at the outset of the disease, instead of waiting till the panic of heavy mortality compelled action.

The proposals made by me to Government last year for arranging as to prompt and correct action by all municipalities for the prevention and repression of epidemics, were referred to a committee for discussion, consisting of Mr. Crole, First Member, Board of Revenue, Surgeon-Major-General Sibthorpe, Surgeon-General with the Government of Madras, Mr. Francis, I.C.S., Acting Under-Secretary to Government and myself. The recommendations of the committee entered fully into the question of finance, sanitary organization and administration, and the outline of sanitary measures to be adopted. The various proposals were then placed before the Municipal Councils by Government for discussion. Final orders have not yet been received.

Government was advised that when an outbreak of cholera occurred at a festival, a special report should be sent to this office as to measures undertaken, irrespective of the ordinary festival report (G.O., No. 296 L., dated 15th February 1895).

The evidence before the "Royal Commission on the water-supply of London," showed that whilst the transmission of cholera by rivers was credited, it was believed that but little evidence was actually on record. I have consequently thought it worth while working out evidence on the point. I have thus been able to show in an irrefutable manner from official records that cholera affected villages in the course of three streams for long distances. An inquiry as to the influence in this respect of the Cauvery (which passes through five districts) has demanded much time in working out, but, so far as I have yet been able to gauge the results, this river must be regarded as an important factor in the spread of cholera in this Presidency.

The impression gained during medical practice, judging by frequency of attention demanded by the two classes, is that on the whole cholera attacks adults more than

children. This is a point that can only be settled by large statistics. An investigation of the ages of 1,000 deaths from cholera was accordingly made, with the result of showing that, with the exception of the first year of life, where in this country nourishment is chiefly derived from breast milk, the incidence is fairly uniform :—

—	Rate per 1,000 of the population of that age.	—	Rate per 1,000 of the population of that age.
Under 1 year of age	0·3	Under 20—30	0·6
1—5	0·6	30—40	0·6
5—10	0·6	40—50	0·7
10—15	0·5	50—60	0·8
15—20	0·6	60 and over	0·5

The gradual increase of small-pox in other parts of India, caused me to send a special warning in May 1895 to all local authorities, pointing out that an invasion of the Presidency might later on be reasonably expected, and advising them to maintain special vigilance as to the appearance of the disease, to attempt segregation wherever possible, and push forward not only vaccination of infants and children, but to impress upon the adolescent population the desirability of practising re-vaccination.

With the object of ascertaining whether I was warranted in pushing re-vaccination, inquiry was made as to the ages of a 1,000 deaths from small-pox gathered from the latest and contrasted with the oldest records available, in the hope that it would be possible to determine how far the absence of re-vaccination had in a partly vaccinated population affected the age of death by small-pox. The result is to show that this influence is already at work though not so demonstrable as in Great Britain, in that the protection of the infantile vaccination although shown up to 20 years rapidly declines :—

—	Per 1,000 of Deaths.		—	Per 1,000 of Deaths.	
	Oldest records.	Latest records.		Oldest records.	Latest records.
Under 1 year of age	3·1	2·7	Under 20—30	0·07	0·08
1—5	1·3	1·2	30—40	0·08	0·08
5—10	0·3	0·4	40—50	0·04	0·06
10—15	0·3	0·1	50—60	0·04	0·04
15—20	0·1	0·09	60 and over	0·01	0·04

An investigation as to the decline of small-pox in municipal towns in this Presidency gave the following statistics, showing marked improvement as time advances :—

Years.	Deaths from Small-pox per 1,000 of the united Populations of Municipalities.		Years.	Deaths from Small-pox per 1,000 of the united Populations of Municipalities.	
1876	1·2		1886	0·7	
1877	—	(Famine year).	1887	0·9	
1878	1·6		1888	0·6	
1879	1·1		1889	0·8	
1880	1·2		1890	1·1	
1881	1·2		1891	1·5	
1882	1·3		1892	1·2	
1883	2·4		1893	0·5	Vaccination compulsory in all Municipalities.
1884	3·9		1894	0·1	
1885	0·9		1895	0·1	

With the prospect of special increase of small-pox following introduction from other presidencies, it remains to be seen during 1896 how far Madras has been capable of resisting the invasion.

The overgrowth of prickly-pear in the neighbourhood of villages is a matter of considerable economical and sanitary importance in this Presidency. I therefore suggested to one of the municipalities the introduction of the cochineal insect for its

destruction. In the course of a search for this insect, I was informed of the destruction of prickly pear said to have occurred in the Ponnéri Taluk. Specimens were obtained through Mr. Sirajudin, Tahsildar of Chingleput. The leaves were found covered with a growth that was pronounced by a local expert consulted to be mycelial. I informed Government of the occurrence and pointed out that as I had no time to make a special investigation on this point, it would be advisable to ask collectors and others to make inquiries in districts as to any parasite likely to be capable of being artificially propagated and applied for the destruction of prickly pear. Subsequently, on the leaves from the Ponnéri Taluk being forwarded to Dr. Watt, Economic Reporter to the Government of India, he declared that an insect (belonging to the genus diaspis) was the destructive agent and proved this by actual experiment. He describes the insect as "voracious," and anticipates it could be propagated at central points and be distributed for the work of destruction over various parts of the Presidency. If Dr. Watt's discovery prove correct, it will prove of vast sanitary utility.

In paragraph 65 of my annual report for 1894, I placed on record the first efforts in this Presidency towards the education of Sanitary Inspectors. The Acting Professor of Hygiene, Surgeon-Captain Robertson, undertook the task of delivering the theoretical course of lectures. As the Professor of Hygiene is employed during the mornings as Assistant Physician at the General Hospital, Madras, I was confronted with the difficulty of securing for the candidates a practical course. Finding this otherwise impossible, I undertook it myself. The President of the Municipality of Madras kindly permitted the class every facility for examining works and apparatus. I was thus able to give aid by taking the students from place to place, and making demonstration as fully practicable as possible.

Since this period the syllabus, which was that of the intermediate test in hygiene of the Government Technical Examinations, has been revised, in consultation with the Director of Public Instruction, so as to secure a grade of study specially suited for sanitary inspectors. Holding in mind the indifferent general education in English of some of the sanitary inspectors employed, in placing the proposal for the teaching of sanitary inspectors originally before Government, I asked that I might be permitted to nominate those who had not passed sufficiently good general educational tests, in cases where I considered sound practical knowledge existed. As, however, I found the applications (as I had anticipated) for entrance to the class to assemble in January 1896 were very numerous, I had no difficulty in declining to exercise the power of nomination, and was thus able to at once raise the standard of general education. I therefore required that, except in the case of sanitary inspectors nominated by municipalities that had been engaged in this work prior to December 1894, none would be received, unless they had passed an examination in general knowledge not lower than the matriculation of the Madras University, were medical subordinates of not lower rank than hospital assistants, or were passed engineering subordinates of not lower grade than sub-overseers. Ninety-six candidates registered their names under these conditions, of whom 61 paid the requisite fees for the theoretical course and examination.

A register has been opened in my office for certificated sanitary inspectors, so that local authorities can apply for their services; 23 municipalies have now certificated sanitary inspectors in their employ. The District Board of Trichinopoly has also, as an experimental measure, employed two as Taluk Sanitary Inspectors for rural sanitation. To ensure that their educational standard should be maintained, I have asked District Medical and Sanitary Officers to kindly undertake the oral examination of these men once yearly. Most of the municipalities have also agreed to my proposal to provide them with the College text books of Hygiene, and the weekly periodical, the "Sanitary Record." By these means, it is hoped they will be kept in touch with advancing hygiene.

The question of re-organization of the Sanitary and Vaccination Department on the lines proposed by the Government of India was referred to me for report at the close of the year. This has been since duly attended to.

In response to my request, Government has been pleased to make a grant of Rs. 2,000 for supply of bacteriological and other scientific apparatus for this office. As the Deputy Sanitary Commissioner, Surgeon-Major Bannerman, has taken leave with the special object of revivifying his bacteriological knowledge in the British schools, it is hoped it will be possible to conduct investigations of the ordinary type in connection with sanitary investigation during 1896.

The work fulfilled by District Medical and Sanitary Officers will be found in the appendix. The amount of inspection fulfilled has decreased more than one-half, in

consequence of Government directing that inspections by these officers should be confined to unions, and that this work should be delegated to their assistants more frequently than hitherto. All reports made by District Sanitary Officers are in duplicate, one report going to the local authority concerned, the other to this office. A reasonable time having been allowed to elapse after receipt of their reports, within which it might be hoped local authorities would have attended to their suggestions, abstracts or extracts as to important items were, during the year, systematically forwarded to the local authorities with the request they would kindly note against each what had been done in the matter.

A valuable part of the work fulfilled by the District Medical and Sanitary Officers consists in the examination of the sanitary conditions of schools, as originally suggested by Surgeon-General Bidie when Sanitary Commissioner. This work fell for some years in abeyance, but on reminding the officers concerned by a special circular of the Government Order on the subject, considerable good work has been the result. Recommendations of this class are usually attended to without demur by local authorities, and will doubtless be productive of considerable good. A little money spent in schools for the provision of object lessons in the form of correctly worked latrines, properly protected water-supplies, and the maintenance of due ventilation and cleanliness, would do a great deal more good than any amount of theoretical teaching of hygiene in schools, although this also has its sphere of utility.

On taking over acting charge in 1893, I invited the attention of Government to the anomalous position occupied by the Sanitary Commissioner of this Presidency, in that schemes were prepared for sanitary works by the Sanitary Engineer without his consulting the Sanitary Commissioner. Government thereupon modified the rules of the Sanitary Board, so as to enable this to be effected. In their Order No. 2380 L., dated 16th November 1894, certain principles were laid down which the Board was directed to follow, and after a short experience definite rules were to be drawn up. These were discussed at special meetings of the Board in June 1895 and received, before the end of the year, the approval of Government. The constitution of the Sanitary Board is such that the Sanitary Commissioner may be readily out-voted by the engineering profession, the President being the Chief Engineer to Government and the only other member being the Sanitary Engineer. There is thus placed a considerable responsibility upon the President of the Board in holding the balance. The rules, however, ensure that the Sanitary Commissioner shall at least have the right to be heard, which is a vast improvement upon the formerly existing condition of affairs. Moreover, as all proposals for sanitary works now pass through the Sanitary Commissioner (as Secretary-General, Sanitation Branch, Sanitary Board) to the Sanitary Engineer (as Secretary, Engineering Branch, Sanitary Board), it is now possible to exert a certain amount of influence as to their character.

The ruling as to sanitary works being drawn up in consultation with the Sanitary Commissioner was not given effect to until subsequent to the meeting of the Board in June 1895; so that works were sanctioned previous to this date for future execution, or are now in progress, which have not been subjected to scrutiny by this office. Since then 117 notes—many being of a lengthy character—dealing with the sanitary aspects of proposed works have been forwarded either to the Sanitary Engineer or the President, Sanitary Board. This work, of course, represents a new tax upon the total time at disposal of this office; but, provided sanitary demands are really met in the works projected in consultation by the Sanitary Board, it could hardly be more usefully consumed.

SANITARY ENGINEERING (1895).

During the year, surveys either for water-supply or drainage, or for both, were completed in three municipalities against four in 1894, and were in progress in three, while additional levels were taken for the water-supply scheme of three others. Of the six schemes, costing in the aggregate Rs. 12,95,000, presented to the Sanitary Board during the year, two schemes for the water-supply of Cuddalore and Tirupati were submitted to Government, and the remaining four, viz., water-supply schemes for Vizagapatam and Bezwada, and the drainage schemes for portions of Tanjore and Kumbakonam, were under the consideration of the Sanitary Board. Besides these, reports were also made (1) on the Hagri and Copper Mountain schemes for Bellary, (2) on the proposed supply of water from the mainland to Cochin, and on the other schemes that presented themselves for the town supply, with rough estimates of costs of

the schemes, and (3) on the proposals to conserve a water-supply area for Kodaikanal. The Conjeeveram water-supply scheme was the only one that was sanctioned for execution during the year. Six water-supply works, estimated to cost Rs. 16,87,850 in the aggregate, were under execution, and of these, the Adoni and Tanjore works were completed, while very little remained to be done at Trichinopoly. Fair progress was also made in carrying out the scheme for the water-supply of Dindigul. In Kurnool, however, fresh estimates for the waterworks had to be prepared and sanctioned during the year in consequence of a change in the site, and work was not begun until near the end of the year. In the case of Conjeeveram, as no trained supervisor was available until November 1895, and as by that time the north-east monsoon had begun, nothing beyond the construction of the drivers' quarters was taken in hand. The improvement of the drainage of Ootacamund received attention, and proposals were made as regards an alternative scheme for the water-supply of Cocnoor. 151 plans and 120 estimates for sanitary works of the aggregate value of Rs. 2,69,342 were scrutinised during the year, as against 100 plans and 102 estimates of the aggregate value of Rs. 1,04,699 in 1894, and new plans and designs were furnished wherever necessary, with the Sanitary Board's proceedings, or separately, as follows:—Hospitals for seven towns, dispensaries for 18 towns, markets for four towns, slaughter-houses for two towns, latrines for nine towns, and miscellaneous plans for eight towns. Type designs for nine sanitary works were issued by the Sanitary Board, and as the type plans and estimates for hospital and dispensary buildings had not been completed by the Consulting Architect to Government, it was found necessary during the year to prepare for temporary use seven plans of different kinds of hospital and dispensary buildings.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1895.

(Surgeon Lieutenant-Colonel J. W. Clarkson.)

General Population.

As directed in Government Resolution in the General Department, No. 2,950, of 8th August 1894, the births and deaths among Europeans and Eurasians are given in a separate paragraph.

Vital Statistics of Europeans and Eurasians.

The European civil population in this Presidency, exclusive of cantonments in quasi-foreign territory, numbers 18,486 persons by the census of 1891. During the year 1895, 358 births and 357 deaths were recorded, a birth-rate of 19·37 per 1,000 and a death-rate of 19·31 per 1,000. By sexes, 191 males and 167 females were born, and as regards deaths 219 males and 138 females died.

The Eurasian population numbers 8,519 persons by the census of 1891, and during the year 1895 the births amounted to 164 and the deaths to 219, or a rate, respectively, of 19·25 and 25·71 per 1,000. Of those born, 94 were males and 70 females, and as regards deaths, 113 males and 106 females died.

The causes from which deaths among Europeans and Eurasians were recorded are given in the following table:—

Causes of Deaths.		Europeans.		Eurasians.	
		Number of Deaths.	Ratio per 1,000 of Population.	Number of Deaths.	Ratio per 1,000 of Population.
Bombay Presidency.	Cholera	—	—	2	0·23
	Small-pox	10	0·54	1	0·12
	Fevers	61	3·30	38	4·46
	Dysentery and Diarrhœa	39	2·11	26	3·05
	Injuries	12	0·65	2	0·23
	Other Causes	235	12·71	150	17·61
	All Causes	357	19·31	219	25·71
Cantonments—Other Causes		4	—	2	—

Of the two deaths registered from cholera, one occurred in the collectorate of Násik and the other in the city of Bombay.

Vital Statistics of Native Population.

Births.—In the Presidency of Bombay, including Sind, during the year 1895 there were 674,304 births registered against 660,268 in 1894. The recorded births for the year under report were thus 14,036 in excess of the number registered in the previous year, and also exceeded the mean of the preceding 10 years ending 1894 by 42,665. By sexes there were 350,115 males and 324,189 females, against 342,911 and 317,357 respectively in 1894.

The following table shows the number of births registered in each year from 1885 to 1895, their ratios per 1,000 of population, and the proportion of males to females :—

Years.	Population.	Number of Births Registered.			Ratio per 1,000 of Population.			In every 100 Births there were		For every 100 Male Births the Females were
		Males.	Females.	Children.	Males.	Females.	Children.	Males.	Females.	
1885 - - -	16,454,414	298,406	274,025	572,431	18·14	16·65	34·79	52·13	47·87	91·83
1886 - - -	16,454,414	303,376	278,177	581,553	18·44	16·90	35·34	52·17	47·83	91·69
1887 - - -	16,454,414	327,500	300,693	628,193	19·90	18·27	38·18	52·13	47·87	91·81
1888 - - -	16,454,414	330,316	304,377	634,693	20·07	18·50	38·57	52·04	47·96	92·15
1889 - - -	16,454,414	312,974	287,515	600,489	19·02	17·47	36·49	52·12	47·88	91·87
1890 - - -	16,454,414	333,698	307,417	641,115	20·28	18·68	38·97	52·05	47·95	92·14
1891 - - -	18,820,346	354,630	328,047	682,677	18·84	17·43	36·27	51·95	48·05	92·50
1892 - - -	18,820,346	337,150	313,517	650,667	17·91	16·66	34·57	51·82	48·18	92·99
1893 - - -	18,820,346	345,424	318,881	664,305	18·35	16·94	35·30	52·00	48·00	92·32
1894 - -	18,820,346	342,911	317,357	660,268	18·22	16·86	35·08	51·94	48·06	92·55
Mean for 10 years	17,400,787	328,638	303,001	631,639	18·89	17·41	36·30	52·03	47·97	92·20
1895 - - -	18,820,346	350,115	324,189	674,304	18·60	17·23	35·83	51·92	48·08	92·59

The recorded birth-rate for the year was 35·83 per 1,000 of population against 35·08 in 1894, and a mean of 36·30 for the previous 10 years.

Of the 24 collectorates and districts the number of recorded births in 1895 was higher than in 1894 in 15, viz.:—Khándesh, Násik, City of Bombay, Admednagar, Poona, Sholápur, Sátára, Ratnágiri, Belgaum, Dhárwár, Bijápur, Kánara, Broach, Kaira, Ahmedabad. The remaining nine collectorates and districts show a decrease as compared with 1894. The registration of births in Sind is apparently defective throughout the province, and especially in the collectorate of Hyderabad. The city of Bombay shows slight improvement in the registration of births over last year. The recorded birth-rate per 1,000 of population for the city of Bombay was 19·07 against 18·35 in 1894, and the mean for the last 10 years ending 1894 was 19·29.

As regards the comparative low birth-rate in the collectorate of Kánara the Deputy Sanitary Commissioner, Southern Registration District, states, "it may be "chiefly explained by the influence of the birth-rate in the forest areas where the "effects of malaria on the mothers is so evident. In the more healthy coast villages "the birth-rate is higher than 30·76 per 1,000, but the general birth-ratio for the "whole of Kánara is brought down by the unhealthy forest villages."

The recorded birth-rates among the urban and rural populations of the Presidency were 29·04 and 36·78, against 27·96 and 36·08 in 1894. Except in the collectorates of Ahmednagar, Ratnágiri, Kánara, Kaira, Karáchi, Hyderabad and Shikárpur, and Thar and Párkar District, the birth-rates were higher among the rural than in the urban population. The same collectorates in 1894, except Kánara and Thar and Párkar Districts, showed an urban birth-rate higher than the rural.

Out of 56 towns in the Presidency, 16 had a birth-rate exceeding 40 per 1,000. Násik, Thána, Mahád, Jacobabad, and Bombay have still very low death-rates.

Deaths.—Among the civil population in the rural, town and cantonment circles in the Presidency, 538,540 deaths were registered during the year 1895. In 1894, 607,179 deaths or 68,639 more than in 1895 were recorded.

The following statement shows the number of deaths recorded in each year since 1885 :—

1885 - - 473,591	1889 - - 518,562	1893 - - 511,831
1886 - - 381,185	1890 - - 463,616	1894 - - 607,179
1887 - - 455,261	1891 - - 513,132	1895 - - 538,540
1888 - - 468,039	1892 - - 611,742	

Of the total deaths registered, 280,866 occurred among males and 257,674 among females, against 316,786 and 290,393, respectively, in 1894.

The computed death-rate per 1,000 of population in 1895 was 28·61 against 32·26 in 1894 and a decennial mean of 28·76. The millesimal rates of males dying to males living was 28·84, and of females dying to females living 28·37. In 1894 these ratios were, respectively, 32·53 and 31·97. For every 100 females who died, 109·00 deaths among males were recorded, but these proportions vary considerably in the following collectorates :—

In Khándesh the ratio of male to female deaths was 111·11 per cent.
„ Thána „ „ 115·75 „
„ Bombay „ „ 112·95 „

In Ahmednagar the ratio of	male	to female deaths	was	112·45 per cent.
„ Kánara	„	„	114·28	„
„ Broach	„	„	110·28	„
„ Kaira	„	„	120·71	„
„ Panch Maháls	„	„	124·44	„
„ Ahmedabad	„	„	114·59	„
„ Karáchi	„	„	116·75	„
„ Hyderabad	„	„	123·56	„
„ Thar and Párkar	„	„	115·11	„
„ Shikárpur	„	„	116·07	„
„ Upper Sind Frontier	„	„	126·69	„

In 1895 the recorded death-rates per 1,000 of population were higher than in 1894 in the collectorates of Ahmednagar and Sholápur, and in the district of Thar and Párkar. The recorded death-rate per 1,000 of population in 1895 was nearly the same as that in 1894 in the collectorates of Sátára, Belgaum, and Dhárwár.

The recorded death-rate per 1,000 of population in 1895 was higher than the annual mean of the preceding 10 years in the collectorates of Khándesh, Násik, Thána, city of Bombay, Kolába, Ahmednagar, Poona, Sholápur, Sátára, and Ratnágiri, and in the district of Upper Sind Frontier. In the collectorate of Belgaum the recorded death-rate for 1895 was about equal to the annual mean for the preceding 10 years. In the remaining collectorates and district the recorded death-rate for 1895 was lower than the annual mean for the preceding 10 years ending 1894.

Deaths by ages.—The mortality amongst children under 5 years of age is high and amounts to 43·43 per cent. of the total deaths, and the infantile mortality under one year is 176·47 per 1,000 living. Under one year the percentage on total deaths was 22·30 against 20·20 in 1894, and in the age-period 1 to 5 years the percentage was 21·13 against 21·27 in 1894. The period of greatest immunity was, as last year, in the age-period of above 10 and under 15, the rate being 7·39 living, or 2·50 per cent. on total deaths. Among old people of 60 and upwards, the percentage on total deaths was 14·81 against 14·66 in 1894.

Deaths by caste or class.—According to the census of 1891 the Muhammadan population numbered 3,501,910 persons, amongst whom in 1895 71,965 deaths were recorded against 80,601 in 1894, the death-rate being 20·55 per 1,000 of population against 23·02 in 1894. The Hindu population amounted to 14,897,629 persons, amongst whom 459,918 deaths or 30·87 per 1,000 of population were recorded. In 1894 the total deaths amongst this race were 520,332, equal to a death-rate of 34·93 per 1,000 of population. Amongst the Christian population numbering 122,089 persons, 2,509 deaths were reported during the year against 2,884 in 1894, the death-rate being 20·55 against 23·62 in 1894. Under the heading "Other Castes" are included all those not belonging to either of the above sects who, by the census of 1891, numbered 298,718 persons, amongst whom during 1895 there were 4,148 deaths against 3,362 in 1894, the death-rate being 13·88 per 1,000 of population against 11·25 in 1894. Among Muhammadans the maximum death-rate during the year (48·84 per 1,000) took place in the collectorate of Násik, and the minimum of 13·10 in Hyderabad. In 1894 the maximum death-rate was 49·00 in Broach, and the minimum 13·62 in the Thar and Párkar district. Among Hindus the maximum death-rate (40·22 per 1,000) was in the collectorate of Sholápur, and the minimum (17·46) in the Thar and Párkar district. In 1894 these rates were in Broach (57·72) and Thar and Parkár (16·32) respectively.

As regards the disproportion in the death-rates of Muhammadans and Hindus in Sind, throughout which province the difference is striking, the Deputy Sanitary Commissioner, Sind Registration District, in his letter, No. 131, dated 15th January 1896, states that "the discrepancies with regard to the recorded deaths among "Muhammadans and Hindus to exist mainly among the rural records. The urban "records show signs of more careful keeping; thus, in Karáchi City, which is the "only town in Sind in which I have a fair control of the registration work, the ratios "of death per 1,000 are, Muhammadans 35·25, and Hindus 32·69. In the other large "towns in Sind the ratios indicate very fairly the amount of attention paid to "registration work by the respective municipalities; thus, in Sukkur the ratios are "Muhammadans 25·37, and Hindus 27·06; whilst in Shikárpur, where the registration "arrangements are very defective, the ratios are Muhammadans 16·76, and Hindus "27·20. As before stated, I have practically no control over urban registration "work outside Karáchi City."

"In the rural circles of Sind, registration is in its earliest infancy and is practically "in the hands of tappedárs and village pátels and mukhis, over whom very little "supervision is exercised with regard to the registration work. The vaccinators "frequently discover discrepancies in the *birth registers*, which discrepancies are "immediately pointed out to the respective collectors, but with regard to the rural "death-rates the vaccinators have little opportunity of applying any check; for the "discrepancies of the rural death-rates the village pátels and mukhis and the "tappedárs can alone be held responsible." He further adds: "In many of the "larger towns and villages of the rural circles the proper census population figures "are not even recorded, consequently the effective checking of the tappedárs' registers "is not possible."

Deaths by causes.—The subjoined table shows the deaths in 1895 arranged according to the specified causes laid down by the Government of India, and contrasted with the results for 1894 and the mean of the preceding 10 years. The causes of deaths will be briefly noticed in the next section:—

Causes of Deaths.	Mean for 10 Years, 1885-1894.		1894.		1895.	
	Number.	Ratio per 1,000 of Population.	Number.	Ratio per 1,000 of Population.	Number.	Ratio per 1,000 of Population.
Cholera	24,848	1·43	33,588	1·78	8,890	0·47
Small-pox	3,186	0·18	3,155	0·17	2,299	0·12
Fevers	349,785	20·10	429,094	22·80	388,848	20·66
Dysentery and diarrhœa	39,475	2·27	34,667	1·84	35,348	1·88
Injuries	5,795	0·34	6,117	0·32	6,051	0·32
Other causes	77,323	4·44	100,558	5·35	97,104	5·16
All causes	500,412	28·76	607,179	32·26	538,540	28·61

Chief Diseases.

Cholera.

Cholera caused 8,890 deaths during 1895, throughout the Presidency, or 24,698 less deaths than in the preceding year. The epidemic prevailed chiefly in the Dhárwár, Sátára, Sholápur, Khándesh, and Ahmednagar Collectorates, where 1,585 or 1·50, 1,354 or 1·10, 1,137 or 1·51, 1,002 or 0·68, and 874 or 0·99 deaths per 1,000 of population, respectively, took place; whilst the minimum mortality occurred in the Broach, Surat, Thána, and Kánara Collectorates, in which there were 1, 5, 53, and 59 deaths, respectively, registered. From the province of Sind no deaths from cholera were reported.

In January a cholera death was reported in Bombay City on the 4th, one in Sholápur town on 6th, and then on 19th in the Ratnágiri Collectorate, in which 33 deaths occurred; 2 more deaths occurred in Bombay City, giving a total of 37 deaths for the month from this cause. In the next month, February, 17 deaths took place in Ratnágiri out of a total of 19 reported for the Presidency, the other cases occurring, one each in Násik and Kaira. In March the cholera ceased in Ratnágiri and other places affected in February, but 29 deaths from this cause were reported from Dhárwár Collectorate, the beginning of an attack which lasted till November. This collectorate does not adjoin Ratnágiri. One death also was reported from Bombay City, and from this month the disease continued endemic in Bombay City to the close of the year. In April 135 deaths occurred in Dhárwár and 2 in Bombay, and in addition the collectorate of Khándesh became affected, 3 deaths being reported, and the disease continuing to the year's end. In the month of May, cholera, besides affecting more severely Dhárwár, Khándesh, and Bombay City, also re-appeared in Násik and Ratnágiri, and deaths were reported for the first time from Kánara, Surat, and Ahmedabad Collectorates, so that eight collectorates were affected and 533 deaths reported. In June, Surat, from which only one case had been reported in the previous month, was free, but except this, the disease prevailed in the same collectorates as in the previous month, and in addition deaths were reported from Kolába, Ahmednagar, Sholápur, and Belgaum Collectorates. The outbreak reached its maximum intensity in Dhárwár and Násik during this month. Eleven collectorates reported 985 deaths.

In July there were no deaths reported in the Kolába and Kánara districts, but the disease broke out fresh in Poona, Sátára, and Panch Maháls districts, and the number of deaths largely increased in Khándesh, Ahmednagar, Sholápur, and Ratnágiri, besides continuing severe in Dhárwár. 12 collectorates were affected and 1,306 deaths occurred. August was the month of greatest intensity. Only in one collectorate, Broach, was the disease reported fresh, but here only one death occurred, and the only death in the collectorate during the year. The number of deaths increased in Khándesh, Ahmednagar, Poona, Sholápur, Sátára, Belgaum, Panch Maháls, and Ahmedabad, but decreased in Dhárwár and Ratnágiri. 1,652 deaths were reported from 13 collectorates. In September, deaths for the first time were reported from Bijápur and Kaira, and there was an increase in the number of deaths in Sátára. In 14 collectorates, 1,043 deaths were recorded.

In October the disease re-appeared in Kolába, Kánara, and Surat districts, and was in every district of the Presidency proper, except Thána and Broach. 1,052 deaths in 17 districts.

In November, Thána, which had escaped so long, though bordered on by Khándesh, Nasik, Ahmednagar, and Poona, was attacked. The deaths in Sholápur, Bijápur, Kaira, Kolába, and Násik increased largely over last month, and 17 affected districts returned 1,485 deaths. In December the cholera ceased in Dhárwár, no death being reported. Kolába reported an increased number of deaths, but though the disease was still in 14 districts, only 608 deaths were recorded.

The death-rate attained the high ratios 1·51, 1·50, and 1·10 per 1,000 of population in Sholápur, Dhárwár, and Sátara Collectorates. In Ahmednagar, Násik, Khándesh and Kolába Collectorates the ratios were 0·99, 0·83, 0·68, and 0·64 respectively. The epidemic although widely prevalent did not show any very serious severity in other parts of the Presidency.

In six towns the cholera death-rate exceeded 2 per 1,000 of population. Of these one is in each of the Khándesh, Ahmednagar, Belgaum, and Dhárwár Collectorates, and two in the Sholápur Collectorate. Out of 56 town circles 26 were affected during the year. The town of Pandharpur in the Sholápur Collectorate heads the number, its death-rate per 1,000 of population having been 17·24.

Out of the 25,143 villages in the Presidency, 729 or 3·47 per cent. were affected by cholera; the highest percentage took place in the Dhárwár Collectorate, where out of 1,299 total villages 143 or 11·01 per cent. were affected. In Sholápur Collectorate out of 713 total villages, the disease appeared in 67 or 9·40 per cent. In the Sátára, Ahmednagar, Poona, Khándesh, and Kaira Collectorates the percentages were respectively 7·89, 5·20, 4·72, 3·54, and 3·28; whilst in the remaining 10 collectorates the percentages were below three.

Small-pox.

During 1895 there were 2,299 deaths from small-pox (1,184 males, and 1,115 females) against 3,155 in 1894, and a decennial mean of 3,186.

The Western Registration District attained a ratio of 0·30 per 1,000 against 0·40 in 1894, and a decennial mean of 0·33. In the Central Registration District the ratio was 0·08 against 0·17 in the previous year, and a decennial mean of 0·13. In the Sind Registration District it was 0·07 against 0·01 in the previous year, and a decennial mean of 0·16. In the Southern and Gujarát Registration Districts the ratios per 1,000 of population were respectively 0·06 and 0·05 against 0·09 and 0·05 in the previous year, and 0·20 and 0·06 the decennial mean. In collectorates the highest death ratio, 0·40, took place in the Kolába Collectorate, and the lowest, 0·01, in the three collectorates of Kaira, Karáchi, and Thar and Párkar. Only the district of Panch Maháls was free. The Presidency rate was 0·12 against 0·17 in the previous year, and 0·18 the decennial mean.

According to age, 26·66 per cent. of the small-pox deaths in 1895 occurred amongst infants under 1 year of age, whilst 54·59 per cent. took place among children over 1 and under 12, the remaining 18·75 per cent. being among persons over 12 years of age.

Fever.

During 1895, 202,528 males and 186,320 females, or a total of 388,848 persons, were reported to have died from fever, against 429,094 in 1894, showing a decrease of 40,246 deaths for the year, the mean for the previous 10 years being 349,785.

In the Central Registration District fever caused a high mortality, 24·45 per 1·000. during the year, against 23·48 in 1894, and the decennial mean 19·33. In the Gujarát Registration District the death ratio was 22·68 against 35·25 in the previous year, and 28·11 the 10 years' mean. In the Western Registration District the ratio for the year was 21·49 against 21·40 in the previous year, and 19·43 the decennial mean. In the Southern and Sind Registration Districts the respective ratios for the year were 16·07

and 15·81 against 17·43 and 16·55 in the previous year, and 16·58 and 17·53 the 10 years' mean. The collectorate of Sholápur heads the list with the high ratio of 30·75 against 27·01 in 1894 and 23·05 in the previous 10 years; and the lowest ratio 7·86 was attained in the town and island of Bombay and 11·06 in the Ratnágiri Collectotate, the Presidency rate being 20·66 against 22·80 in the previous year, and 20·10 the decennial mean.

Excepting in the month of December, the deaths from fever were below the corresponding months of 1894, and excepting the month of November they were above the mean. The maximum mortality from fever took place in December, when 37,307 deaths were reported, and the minimum in February, when 28,438 deaths were recorded from this cause.

Dysentery and diarrhœa.

During 1895 dysentery and diarrhœa caused the deaths of 18,943 males and 16,405 females, or a total of 35,348 persons against 34,667 in 1894 and a decennial mean of 39,475.

The Central Registration District heads the list with a ratio of 3·22 per 1,000, against 2·55 in 1894 and 2·15 the decennial mean. The Western Registration District comes next with a ratio of 2·50, the Southern Registration District 2·10, Gujarát Registration District 0·18, and the Sind Registration District 0·14. In the Presidency the rate was 1·88 against 1·84 in the previous year and a decennial mean of 2·27. In the collectorates of Ahmednagar, Poona, Sholápur, Sátára, Ratnágiri, Belgaum, Dhárwár, Bijápur, Kánara, Karáchi, Hyderabad, and Shikárpur the death-rate for the year was slightly higher, and in the rest it was below 1894. High ratios were recorded in Sholápur 4·34, Sátára 3·88, Belgaum 3·65, Násik 3·64, Ahmednagar 3·42 and Khándesh 3·09, and the lowest 0·06 in Thár and Párkar and Shikárpur, and 0·04 in Panch Maháls and the Upper Sind Frontier.

During the five months from August to December the deaths from dysentery and diarrhœa exceeded those recorded in 1894, but in other months, and excepting July, August and September of the mean, they were less than in 1894 and the 10 years' mean. The maximum mortality occurred in August and the minimum in February.

Injuries.

During 1895, 3,494 males and 2,557 females or a total of 6,051 persons met with violent deaths. The mortality from these causes is less by 66 than that reported in 1894, when 6,117 deaths were recorded. Of the 6,051 deaths, 2,410 happened from drowning, 1,380 resulted from snake-bites, 532 from wounds, 170 from hanging, 140 from poisoning, 80 from attacks by wild beasts, and 1,339 from causes not specified.

Other causes.

The recorded deaths from causes other than those specified number 97,104, of which 50,044 occurred among males and 47,060 among females. The total for 1894 was 100,558, so there is a decrease of 3,454 under this head.

Sanitary Works.—Military and Civil.

All available information under these sections has been thrown in a tabular form, and will be found in Appendices Nos. IV.—V. and the last four columns of Annual Form II., Appendix VI.*

It will be seen from the statement given in Appendix V. that in the 168 municipalities in the mofussil there was a population of 2,237,838 souls and an income of Rs. 47,49,303. Out of this income Rs. 21,50,827 or 45·28 were allotted for sanitary works, and out of this allotment Rs. 18,21,963 or 84·71 per cent. were spent.

Of the total expenditure Rs. 8,69,219 or 47·71 per cent. were spent on conservancy, Rs. 4,96,543 or 27·26 per cent. were spent on improvement to water-supply, Rs. 2,15,979 or 11·85 per cent. were spent on improvement of town-sites, Rs. 77,961 or 4·28 per cent. were spent on construction and repairs to markets and slaughter-houses, Rs. 8,130 or 0·45 per cent. were spent on sanitary arrangements during fairs and festivals, and Rs. 15,431 or 8·45 per cent. were spent on other sanitary objects, including construction and repairs of tanks, &c.

The Bombay Village Sanitation Act, 1889, has been introduced, up to the end of 1895, in 163 villages. Under this Act, if the villagers agree to provide three-sixths of the cost and the local board two-sixths, the provincial fund adds the remaining one-sixth, the principal conditions being that there must be residents in the village willing and competent to serve on the Sanitary Committee and that there are good prospects of benefit arising from the application of the funds provided. The benefits

* Not reprinted.

to be conferred are preserving the purity of the water-supply and attending to the conservancy of the village, and by inducing the leading people of the village to move up the matter, thus to spread an interest in sanitation amongst the people themselves.

Sanitary Board.—During the year the Sanitary Board gave advice on projects for improving the water-supplies at Dakor, Kirki, and Alandi, and on a scheme for supplying Yeola with a water-supply. They also advised on the experimental drainage scheme for Ahmedabad, which has since been approved and sanctioned, at a cost of Rx. 2788; the drainage and sewerage of Parel, a drainage project for the town of Dhulia, a project for constructing an intercepting drain at Nasik, to form the first portion of the complete drainage scheme of that town, and the question of house connections of the Government buildings with the sewerage system of Colaba, with the view of stopping the present system of hand removal of night-soil at Colaba. The Board also gave advice on a number of miscellaneous projects.

Abstract of Report of the Health Officer of the Port of Bombay for the Year ending 31st December 1895.

The following table gives a summary of the shipping and health of the Port of Bombay, and of the work in connexion therewith, for the year ending 31st December 1895 :—

Table No. 1.

Vessels including Native Craft.	Number.	Number of Passengers as far as is known.	Number of Vessels inspected.	Number of Persons, including Crew, on Vessels inspected.	Number of Vessels disinfected.	Number of Persons vaccinated.	Diseases and Number of Cases of each.						
							Cholera.	Small-pox.	Measles.	Scarlatina.	Chicken-pox.	Enteric Fever.	Cardiac disease.
Entered - - -	48,210	460,483	20	19,140	7	864	11	3	21	1	2	1	1
Left - - -	40,768	418,745	540	80,876	—	—	—	—	—	—	1	—	—
		Including Harbour Population.											
In harbour during the year -	1,339	22,142	12	—	12	15	11	4	—	1	2	—	—
Total - - -	90,317	901,370	572	100,016	19	879	22	7	21	2	5	1	—
1894 - - -	86,560	884,428	661	116,140	39	124	29	4	30	—	2	1	—

In the above table the number of crew on board ships entering the harbour during the year is not shown, as no record is kept.

The discrepancy between arrivals and departures is explained by harbour boats arriving from across the harbour with wood, grass, and other local cargo. On arrival they are noted as "arrivals," and having discharged their cargo depart for similar cargo without being noted as "departures."

Of the 460,483 passengers who are shown in the foregoing table, 14,434 were troops, 10,826 Mecca pilgrims, and the remaining 436,223 principally passengers from ports in close proximity to Bombay.

Infected arrivals.—The following table shows the number of ships which had infectious disease on board on or before entering the harbour :—

Class of Vessels.	Number of Ships.	Total Number of Crew and Passengers.	Diseases and Number of Cases of each.							Number of persons vaccinated.
			Cholera.	Small-pox.	Measles.	Scarlatina.	Chicken-pox.	Enteric Fever.	Sudden death from cardiac disease.	
1. Troop ships -	2	2,892	—	—	21	1	—	1	—	—
2. Pilgrim ships -	2	1,791	—	2	—	—	—	—	—	848
3. Other vessels -	5	635	11	1	—	—	2	—	1	16
Total - -	9	5,318	11	3	21	1	2	1	1	864
1894 - -	21	7,912	—	3	21	—	1	1	—	110

The above table does not include the cases of infectious disease which occurred on vessels in the harbour, or amongst the harbour population. These will be noticed under vessels in port.

The small-pox cases were removed to hospital on shore, and the ships were disinfected, and those on them unprotected by previous small-pox or vaccination were vaccinated. During the year, 864 persons on board such vessels were vaccinated. The cases of measles on board of Her Majesty's Indian troopship were landed and isolated in the Military Cantonment at Colába. The cholera cases shown in the foregoing table occurred among the firemen on board of the "Bancoora" a few days after she had left Calcutta for Bombay. The deck crew did not suffer from it, although they had used the same water and food. The actual cause of the outbreak could not be traced, but the firemen themselves attributed it to the use of Calcutta coal which was used in the furnaces. The clothes of four persons who died of the disease were destroyed, and the clothes belonging to those who recovered, as well as of the crew generally were fumigated and washed in carbolic lotion. The ship was thoroughly disinfected.

No vessels arrived with suspicious cargo, such as hides of cattle supposed to have died of or suffered from contagious cattle-disease, nor did any vessel arrive with glandered horses during the year.

The following table furnishes the details of the outward bound vessels inspected and granted Form B. bill of health during the year.

Table showing the number of crews and passengers of outward square-rigged vessels and steamers leaving, and of native sailing craft bound for quarantine ports inspected during the year ending 31st December 1895. This includes 26 pilgrim vessels for Jeddah. By quarantine ports are meant—ports of Mauritius, Aden, Red Sea, Europe *viâ* Canal and Persian Gulf—vessels for which, with their crews and passengers, are inspected on the day of sailing before bills of health are granted.

Names of Ports to which sailed.	Number of vessels.	Number of Tonnage (net).	Number of Individuals comprising Crews.	Number of Passengers.	Total of Crews and Passengers.
I.—Square-rigged Vessels and Steamers.					
Europe, viâ the Suez Canal	228	544,988·73	18,777	6,937	25,714
Aden	37	64,521·56	5,210	2,088	7,298
Red Sea ports	9	10,053·97	614	278	892
Suez	—	—	—	—	—
Port Said	2	3,766·61	52	—	52
Mauritius	14	16,939·48	852	1,024	1,876
Persian Gulf	36	40,544·31	821	1,993	2,814
Total	326	680,814·66	26,326	12,320	38,646
II.—Pilgrim Ships with 60 or more adult passengers.					
Jeddah, viâ Aden	26	31,314·88	1,721	17,287	19,008
Total	26	31,314·88	1,721	17,287	19,008
III.—Native Sailing Craft.					
Persian Gulf ports	90	14,117·68	1,994	243	2,237
Other foreign ports	80	9,136·76	1,840	210	2,050
Total	170	23,254·44	3,834	453	42,87
IV.—Her Majesty's Indian Troop, and Marine Ships, and British and Foreign Men-of-War.					
Europe, viâ the Suez Canal	15	57,118	3,282	15,368	18,650
Aden	2	1,371·04	124	81	205
Persian Gulf	1	715	80	—	80
Total	18	59,204·04	3,486	15,449	18,935
Grand Total	540	794,588·02	35,367	45,509	80,876
1894	582	894,692·36	36,961	44,017	80,978

In addition to the above, Form C bill of health was issued to 666 vessels. It is usually taken by vessels bound for Indian, China, and East African ports, where quarantine restrictions are mild, or are only put in force against arrivals from places where epidemics are actually prevailing. The total number of bills of health issued, including form B, was, therefore, 1,206 against 1,177 in the year 1894, and 1,176 in 1893.

The remaining vessels, 39,562 in number, took no bill of health, as they were generally native coasting craft and Shepherd's ferry steamers.

The bills of health, Form B, furnished to the vessels shown in the foregoing table were invariably clean bills, as at no time during the year did the Medical Board declare cholera to have been epidemic in Bombay. But attached to each bill of health was a certificate showing the number of deaths from cholera, yellow fever, and plague in Bombay during the previous week. This necrological certificate has to be produced at certain ports.

During the year, on inspection of outward vessels immediately prior to sailing, no cases of infectious disease dangerous to life were discovered.

The sanitary condition of outward bound vessels was as a rule fairly satisfactory. The principal defects noticed were overcrowded forecastles, faulty construction of crews' quarters, conveyance of deck-passengers on long voyages without suitable accommodation, foul-bilges in native craft.

Infectious Disease on Vessels in Port.—There were 11 cases of cholera, seven of which proved fatal, amongst a harbour-population estimated at 22,142. 10 cases occurred on board native harbour-boats and one on board a steamer belonging to the British India Company. All these vessels were disinfected as thoroughly as possible. Out of the 11 cases, eight received treatment in the Infectious Diseases Hospital, and the remaining three were returned as having died in their boats a few hours from the beginning of the attack. One of the two cases of chicken-pox occurred on board of one of Her Majesty's marine ships. The case of scarlatina was reported to have been removed to the Saint George's Hospital from one of the Indian Troop Service transports on the day of departure from this port. In connexion with the four cases of small-pox, 15 members of the crew of only one ship were vaccinated.

The following table, which deals only with cholera infected harbour-boats lying about the various bandars, shows how high the mortality is amongst those who have suffered from the disease during the last 11 years:—

Years.	Cases.	Deaths.	Percentage of Deaths amongst those attacked.
1885	30	26	86
1886	2	2	100
1887	26	21	80
1888	15	10	66
1889	23	21	91
1890	3	2	66
1891	5	5	100
1892	12	12	100
1893	12	12	100
1894	28	22	78
1895	10	7	70
TOTAL	166	140	84

There may have been a number of mild cases which ended in recovery, and as such were not reported. The usual mortality in cases of cholera attacks in India is about 40 per cent.

Disinfection of Ships and General Health of the Shipping.—Nineteen vessels of various sorts were disinfected during the year on account of infectious disease dangerous to life. The disinfection of ordinary vessels and harbour boats was as usual satisfactorily carried out by the Water Police in accordance with the instructions given by the Health Officer of the Port. The Naval authorities dealt with the disinfection of Her Majesty's Marine and Indian troopships on which infectious disease occurred. None of these ships were kept in quarantine for any time and were only detained for a few hours while they were undergoing the necessary disinfection.

The general health of the harbour population was reported as satisfactory during the year. The Saint George's Hospital during that time admitted 537 Europeans

connected with the shipping and harbour, of whom 24 died; whilst the Goculdáss Tejpál Hospital admitted 197 Natives, of whom eight died and the Jamsetji Jijibhoy Hospital 103 Natives, of whom 10 died. The total number of admissions into these hospitals and deaths were, therefore, 837 and 42 respectively. The principal causes of admission were as usual due to accidents, bowel complaints, venereal diseases, fever, rheumatism, bronchitis, and affection of respiratory system.

Dr. Shroff, the Medical Inspector of Seamen, has reported that there was an outbreak of typhoid fever amongst the mariners of Her Majesty's Ship "Cossack" while quartered in the Royal Alfred Sailors' Home from 15th January to 9th March 1895. Thirty cases in all were sent to the Saint George's Hospital. A committee was appointed by the Rear-Admiral Commander-in-Chief, East India Station, to inquire into the cause of the outbreak. The Committee arrived at the following conclusion :—

"The conclusion formed from the foregoing investigation is, that the outbreak of the enteric fever amongst the ship's company of Her Majesty's Ship "Cossack" is most probably due to an article of diet.

"We are of opinion that the milk is the most likely source of infection; but the watercress may also be a possible source owing to the conditions under which it is grown."

Dr. Shroff thinks that the investigation was somewhat incomplete, as the question of the sanitary condition of the vessel on which the persons attacked had been at work was overlooked by the committee.

Dr. Shroff has also reported that during last year he examined 775 native lascars for service on steamers before they signed Articles. Of these 775 persons he had to reject 110 for heart and venereal diseases, weak chest, and other causes. He mentions that out of the number he had rejected during 1894, 33 per cent. suffered from venereal diseases. During the year 1895 the percentage increased to 42·81, and he observes that the disease has been freely contracted by domestics ashore.

Quarantine against Bombay.—No quarantine was imposed at Suez against Bombay during the year 1895.

No complaints were made by ship captains or agents of vessels—other than those of certain pilgrim ships—of any delays due to quarantine regulations at foreign ports caused to their steamers which left this port in possession of official bills of health, with the exception of the Anchor Line S.S. "Australia" which was detained in quarantine for three days owing to the captain having produced a Turkish bill of health at Barcelona, although he had a clean Government bill of health from Bombay.

In accordance with their resolution, in the General Department, No. 5,496, dated 17th December 1895, Government have finally declared Pir Pao to be the Quarantine Station for the purposes of the B. Quarantine Rules, and have retained for that purpose at Pir Pao the land measuring 9¼ acres as per their resolution, Revenue Department, No. 117, dated 7th February 1896.

The following table shows the number of days during which quarantine was in force at Suez against arrivals from Bombay since the year 1884, with the Bombay cholera deaths of each month :—

Years.	Number of Days at Suez during which Quarantine was in force against Bombay.	Total Number of Cholera Deaths in Bombay City for the Year.*	Number of Cholera Deaths in Bombay City for each Month.											
			January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.
1884	250	576	101	33	34	7	70	19	8	73	94	47	50	40
1885	227	598	49	80	149	114	62	23	53	34	20	11	1	2
1886	13	19	3	2	—	1	2	2	—	—	5	—	1	2
1887	66	269	—	1	2	3	1	8	45	103	48	41	15	2
1888	6	379	5	1	10	36	40	54	38	75	68	16	7	29
1889	113	462	108	29	8	14	26	34	108	67	32	12	13	11
1890	Nil.	102	40	15	9	—	1	3	12	7	7	2	1	5
1891	18	146	1	1	4	1	1	1	6	33	73	19	6	—
1892	Nil.	169	1	2	1	12	17	12	26	29	29	27	10	3
1893	Nil.	147	4	—	3	23	23	10	11	31	35	6	1	—
1894†	Nil.	426	1	1	2	8	53	61	134	131	22	8	3	2
1895	Nil.	90	3	—	1	2	8	1	3	8	4	12	38	10

* Including European and Eurasians.
† Cholera was declared to be of an epidemic form between 17th July and 7th August 1894.

Red Sea Pilgrim Traffic.—Twenty-six steamers left with 17,102 souls (pilgrims) for Jeddah and 185 others, principally native troops and followers, for Aden. This is the second largest number of pilgrims which has left Bombay for Jeddah in any one year. The steamers were of the usual class engaged in the trade with the addition of two new vessels, the "Moshtari" and the "Ajmir." On the whole the vessels were fairly well ventilated and provided accommodation at the rate of 9 square feet in the 'tween deck and 6 square feet on the upper deck, or 15 feet in all for each adult pilgrim. The Turkish steamer "Abdul Kadar" made but one trip, and to enable her to carry a fairly large number of pilgrims under the Indian Rules, she had to expend a considerable amount in making alterations and repairs on board.

There is still room for improvement in the ventilation of the 'tween decks of pilgrim ships. Shipowners complain that their ships' decks are damaged and rendered dangerous by being cut up for the large number of small ventilators that are required to give air to the 'tween decks. These tin funnels are screwed into the deck and have to be removed in rough weather. What is required in the absence of machinery for ventilating purposes is a system of substantial iron-shafts, say 6 feet by 2 feet, extending some 12 feet above the deck. These air shafts would not hurt the deck and they could be fitted up against deck houses so as not to be in the way when cargo is being worked. Pilgrims are not an over clean or healthy lot, and as such they require more space and better ventilation than either Native troops or emigrants, who are generally men in the prime of life.

The pilgrims were drawn from all classes of Indian and Central Asian Muhammadans, and in addition an English woman, Australian born, was found among the third-class passengers making the voyage as a pilgrim. She was very purdá, would not give any account of herself, and said she could not speak Hindustáni. The general health of the pilgrims was fairly good. The usual number of very old and young, lame and blind were observed among them. Some owners have taken to removing from their ships pilgrims, who, although free from infectious disease, are in a dying or very feeble condition. Stowaways were numerous during the year. A large Sindi was found in a state of collapse in a box 2 feet 9 inches by 1 foot 7 inches and 1 foot 4 inches. He was removed and resuscitated.

The Haj of 1895 took place on the 4th June and Camaran was opened for the reception of the pilgrims on the 28th December 1894. The usual outbreak of cholera occurred while they were undergoing quarantine at Camaran. Pilgrims on three of the 26 vessels which left Bombay were declared infected with cholera, but this was after they had been on shore for some time.

There were 484 admissions into hospital on board ship and 61 deaths out of the 17,102 pilgrims. The death-rate is therefore 3·56 per 1,000 per voyage. The average duration of the voyages to Jeddah, exclusive of the usual 10 days spent on shore in quarantine at Camaran, was 13½ days. The most common causes of admissions into hospital were fevers, diarrhœa, dysentery, and injuries. As usual the majority of the admissions from diarrhœa and dysentery took place between Camaran and Jeddah which is only a two days' voyage; while the pilgrims were in the lazaretto 147 more died, cholera having claimed 72 of the number. During the prevalence of cholera at Camaran, Government placed a Muhammadan Hospital Assistant at the disposal of the Port Health Officer. He was utilised for observing the pilgrims at the various rest-houses and mussáfferkhánas in the city.

The following is a short history of the outbreak of cholera at Camaran. A very able and full report of this outbreak by Surgeon-Major MacCartie is now before Government.

Cholera is said to have broken out among the pilgrims of three vessels and to have first appeared at Camaran amongst the pilgrims of S.S. "Mahommedi." This vessel left Bombay on 6th March and arrived at Camaran on the 16th idem. She had three deaths during the voyage, one from debility (age 80) on 8th, one from pneumonia on the 8th, and one from phthisis of lungs on the 15th March. On 23rd March, or seven days after landing at Camaran and 17 from departure from Bombay, two of her pilgrims died in lazaretto from diarrhœa; and on 24th the sanitary officials declared cholera to have broken out, and imposed 15 days' additional quarantine from that date. Cholera cases occurred at intervals with resulting fresh periods of quarantine up to 8th April; and the vessel finally re-embarked her pilgrims on 24th April and arrived at Jeddah on 27th April, having undergone at Camaran a period of 39 days' quarantine, during which time according to the report made to the Commander by the Camaran officials 54 of her pilgrims died, and of these 28 succumbed to cholera. It is worthy of notice that cholera cases are said to have occurred at Mecca on the 21st April and at Jeddah at an earlier date when the "Mahommedi" pilgrims had not even arrived at the latter port.

The next ship was the "Jubeda," which left Bombay on 16th March and arrived at Camaran on 25th of same month. On the voyage to Camaran three deaths occurred—old age (two), ages 75 and 85, and phthisis of lungs (one); dates of deaths in order of disease 22nd, 24th, and 23rd of March. The Medical Officer gave medical treatment to 39 pilgrims on the voyage to Camaran, and not one of these had any diarrhœa or symptoms suspicious of cholera. On the 30th March, or five days after landing at Camaran and 14 days from departure from Bombay, cholera broke out amongst the Jubeda's pilgrims, and lasted until 26th April with corresponding quarantine. Finally on 11th May the quarantine was raised, the vessel re-embarked its pilgrims and arrived at Jeddah on 13th May, having been in quarantine at Camaran for 47 days, during which time, according to the Camaran officials, 29 of her pilgrims died of cholera and 16 of other diseases.

The "Huseinee" left Bombay on 10th April and arrived at Camaran on 18th idem. During the voyage she had no deaths, and no pilgrims required medical treatment. On 24th April, *i.e.*, on the 6th day of quarantine, and on the 14th day from departure from Bombay, cholera broke out amongst her pilgrims in camp, and lasted with fresh imposition of quarantine until 25th May. Finally on 31st May, as it was clear that the 15 days' quarantine imposed after each case would, if reckoned from the 25th, prevent the pilgrims reaching Jeddah in time for the Haj, the vessel re-embarked her passengers and returned to Bombay without the pilgrims having been able to perform their Haj. They had been for 43 days in quarantine at Camaran, and 22 of them had perished, 15 from cholera and seven from ordinary diseases, all victims to an insanitary quarantine station.

The three vessels, it should be stated, on the voyages to Camaran had only touched at one intermediate port, viz., Aden.

The "Mahommedi," "Jubeda," and "Huseinee" are amongst the very best pilgrim liners in the trade, and their sanitary condition when examined prior to the embarkation of their passengers at Bombay was excellent.

The pilgrims were free from cholera while on board ship, and it was only after being on shore for a period of from five to seven days that it made its appearance among them. The crews of the three ships had the protection of the pure drinking water on board and remained free from the disease, while the pilgrims, who were provided with an indifferent water-supply, were suffering from it on shore. Camaran as a compulsory quarantine station should be abolished, as the drinking water is bad and the sanitation primitive. If it is found impracticable to cease using it for quarantine purposes, condensed water should be issued to the pilgrims and the administration of the island placed in the hands of some authority who would be capable and willing to improve the sanitary condition of the lazarettoes. The present quarantine fees would be more than sufficient to meet all expenses.

Sanitary State of the Harbour and Foreshore.—The sanitary defects of the docks, harbour and foreshore were noticed in the reports for the years 1893 and 1894. The bad corners and berths of the docks were dredged, and no complaints were made of ill-health on board ship or amongst the dock employés. The Port Trustees appointed a special officer to see that the closets of ships were locked while the vessels were in docks. Eleven latrines with about 40 seats have been erected at sites where they were most urgently needed. Mody Bay South Reclamation, which was extensively polluted, has been taken up for the bulk oil installation, and will, therefore, cease to be a nuisance. The swampy foreshore at Mázagaon and Tank Bandars has been reclaimed, and this part of the foreshore has been vastly improved. The mangrove bushes at Sassoon Dock have been removed. The drain for the tramway company's stables has ceased to discharge into the Arthur Basin. This drain was the cause of periodical complaints in former years from the inhabitants of Grant Buildings. The following basins have been dredged; viz., Sand, Chunam, Carnac and Kerosine. Kására basin remains as foul as ever, and will continue so until such time as it is filled in for the proposed new railway, or until the drain is diverted into the Mázagaon Drainage System, which is to be undertaken at some future date.

The sanitary condition of the port has markedly improved during the year, and the Port Trustees deserve full credit for this improvement. The municipal and private drains they apparently cannot interfere with. The retarding elements in the sanitary improvement of the port and foreshore are private owners and the Municipal Corporation. During the year the Pilgrim Ships Act, 1895, received the assent of His Excellency the Governor General in Council, but it has not been brought into force up to the present.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1895-96.

(*Mr. H. C. Williams, Chairman.*)

Town and Bustee Improvement.—In the miscellaneous Capital Budget for 1895-96 the Commissioners sanctioned Rs. 3,92,595 for new drainage and bustee improvements of the town proper as required under Section 37 of the Act (Clause 3). Out of this sum Rs. 45,402 were allotted for bustee and town improvements, besides Rs. 50,000 on account of petty town improvements, allotted from the revenue. The expenditure actually incurred and adjusted in the accounts has been Rs. 74,084-1-4, of which Rs. 21,042-14 were spent on bustee improvements.

Bathing platforms.—The Commissioners have commenced the construction of new bathing platforms at Gazir Naziboolla's Lane and in Maugpara Bustee. Orders have also been issued to prepare estimates for two more—one in Bysack's Lane and the other in Baug Bazar Street, municipal land being available in both cases. The bathing platform at Jorapooker Square has been thoroughly repaired and opened to the public.

Tanks.—Only two tanks, one at 9, Belvedere Road, and the other at 27, Omda Rajah's Lane, were completed during the year.

Waterworks.—The erosion of the river bank at the Pultah Works still causes some anxiety. During the year the banks have been repaired as far as practicable by cutting the banks to a slope and pitching with stone. The length of (filtered) water main now in use amounts to 310·59 miles, 3·59 miles having been laid during the past 12 months. The number of premises connected during the year amounted to 996, and the total number of premises connected is now 26,312. The average daily consumption of filtered water during the year was 20,284,181 gallons. The consumption per head per day works out at 50·09 gallons for the town proper and 20·11 gallons for the added area.

There has been a great demand for unfiltered water during the year; in fact the demand has exceeded the supply. The consumption during the year was 5,692,151 gallons a day. The length of the unfiltered water mains has been increased by 1·54 miles, and the total length of main is now 75·17 miles. In connexion with this main there are now connected 1,216 premises, 151 public conveniences, 86 bathing platforms, 289 sewer flushing chambers, and 2,911 ground hydrants for road watering and sewer flushing purposes. The consumption per head per day (unfiltered water) amounts to 13·43 gallons.

Drainage and General Construction.—The drainage of the Entally Block has been completed so far as it has been sanctioned, and the Bahir Mirzapur scheme has also been completed. The sewers now measure 208·797 miles, including 9·25 miles of bustee sewers. The number of premises connected to sewers during the year was 528, making the total number of connections 29,140. The number of premises connected under the new rules amounted to 73 for the year, or a total number of 988. The drains of premises were examined by the Inspectors during the year, and in 3,071 cases or 47 per cent. defects were found. About 8 miles of kirb and channel stones have been laid in streets. The additional sewers laid during the year measured 1·17 miles, and 1·67 miles have been relaid and re-modelled.

Mr. Hughes' report on the drainage of the suburbs was submitted to Mr. Baldwin Latham for his opinion thereon. This opinion was received in September 1895, and a joint report by Messrs. Hughes and Kimber was prepared dealing with Mr. Latham's suggestions. A pail and cart depôt was constructed at the Budge-Budge Road, and a cast-iron main was laid to discharge the sewage into the Circular Road sewer. The pumping machinery is now in course of erection.

Roads.—There are now 328 miles of roads within the municipal limits of which $103\frac{1}{2}$ are stone metalled, $164\frac{1}{2}$ brick metalled, $35\frac{1}{4}$ over sewered ditches, and $24\frac{3}{4}$ unmetalled.

Vital statistics.

The health of the town was very unsatisfactory, the deaths being as high as 39·6 per 1,000 during 1895, while the birth-rate declined to 16·0 per 1,000. These figures are respectively the highest and lowest known since the amalgamation of the suburbs. The total number of deaths was 27,031, and was made up as follows :—

11,345	deaths from	fevers = 16·6 per	1,000 of population.
2,099	do.	cholera = 3·0	do.
2,220	do.	small-pox = 3·2	do.
3,269	do.	diarrhœa and dysentery = 4·7	do.
8,098	do.	all other causes = 11·8	do.
27,031	Total number of deaths.		

It is noticeable with regard to this that the average price of food was higher in the year than the average of the 10 preceding years, being Rs. 3-12 against Rs. 3-9-4.

The increase from fever was especially noticeable in the canal area of the town, where the deaths amounted to 27·0 per 1,000 of the population.

The supply of good water, so much in advance of good drainage, has largely discounted the advantages to be derived from the improved supply.

The deaths from cholera amounted to 2,099, of which 1,302 were in the town and 797 in the suburbs. The Health Officer has pointed out that, besides the numerous polluted tanks, the influx of pilgrims into the town, and the presence of cholera microbes at the bathing-ghâts add to the chances of the spread of the disease. It will be difficult to drive away these causes of the disease, though the Health Officer hopes they will be diminished.

Two thousand two hundred and twenty persons died from small-pox. Of these, 501 were vaccinated, 420 inoculated, and 1,217 unprotected. Among the latter children especially suffered, being no less than 708. At the "Campbell Hospital" more accurate statistics are taken, and from there it was ascertained that recorded vaccination reduced the mortality by nearly six times.

All available precautions were taken during the year to check the progress of disease.

Vaccination was vigorously pushed on, the number of persons vaccinated being 54,982 against 17,335 in the previous year. 88·88 per cent. of the cases were reported successful in the case of primary vaccinations. Prosecutions for non-vaccination decreased from 562 in 1894 to 321 in 1895, being undoubtedly due to the prevalence of small-pox. There is an increased demand for animal virus every year.

Professor Haffkine's method of inoculation as a prophylactic against cholera was also carried on during the year 1895, when 2,038 inoculations were performed.

ABSTRACT OF REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1895.

(*Dr. W. J. Simpson.*)

LIBRARY OF THE BOMBAY

Meteorology.

The variations in the atmospheric pressure during the greater part of the year were small, the lowest reading, 29·565, being recorded in July, and the highest, 30·009, in January and December. The mean daily variations of temperature were greatest from January to May and in November and December, and least in August. The mean daily dew-point was highest in July, August, and September, and the mean maximum solar radiation was highest in May. Rain fell during all the months except January, November, and December, the number of rainy days during the year amounting to 110. The maximum monthly total rainfall and the maximum fall in 24 hours both occurred in August.

Price of food.

The price of food was higher in 1895 than the average of the preceding 10 years. Common rice sold on the average at Rs. 3-12 against Rs. 3-9-4 per maund. Fuel sold at an average price higher than, and salt at about the same price as, the average of the previous 10 years. The average price of meat, fruit, fish, and vegetables was higher than the average of the 10 years from 1885 to 1894.

Vital statistics.

The number of births (born alive) recorded during the year 1895 was lower than that recorded during any of the previous six years. There were 10,945 births, giving an annual birth-rate of 16·0 per 1,000 of population. The figures for the past seven years are as follows:—

Year.	No. of Births.	Birth-rate.	Year.	No. of Births.	Birth-rate.
1889	12,317	18·0	1893	13,492	19·7
1890	11,918	17·4	1894	11,438	16·8
1891	12,477	18·3	1895	10,945	16·0
1892	12,688	18·6			

As usual, the greatest fertility was exhibited by the Christians and Other Classes and by the Hindus more than the Muhammadans. According to locality, the birth-rate was greatest in the added area of Burtola, in Hastings, and in the town area of Burtola, and was least in Burrabazar, Waterloo Street, and added area of Moocheepara.

The general health of the town was not good during the year 1895. There were 27,031 deaths, being a mortality of 39·6 per 1,000 of the population, against 22,441, or a ratio of 32·9 in 1894, and against 20,924, or a ratio of 30·7, the mean of the five years 1890 to 1894. The following statement shows the numbers of deaths and death-rates in Calcutta during the past seven years:—

Year.	No. of Deaths.	Death-rate per 1,000 of Population.	Year.	No. of Deaths.	Death-rate per 1,000 of Population.
1889	19,564	28·7	1893	20,103	29·5
1890	20,368	29·8	1894	22,441	32·9
1891	21,517	31.5	1895	27,031	39·6
1892	20,180	29·6			

The decline in the public health in comparison to the previous year was greater in the suburban amalgamated area than in the town proper, and in the area bordering on

the Circular Canal than in the rest of the suburbs. The death-rate in the town proper rose to 35·8 in 1895 against 30·0 in 1894, while the death-rate in the suburban area rose to 47·8 in the year 1895 against 39·0 in 1894; and the ratio in the canal area was 46·4 against 35·2, and in the rest of the suburbs was 48·0 against 39·7. In comparison with the year 1894 the unhealthiness was not confined to any particular ward of the town. For, if the mortality of 1895 is compared ward by ward with that of the previous year, a rise in the death-rate is to be noted in all the wards. In comparison with the mean of the preceding five years, an increase in mortality occurred in all the wards except Alipur, where there was a fall of 4·5 per 1,000 of population.

As usual, the mortality among females was higher than among males, the ratios being 48·9 and 34·7 respectively. The excess in mortality during 1895 over the previous year was due to an increase in the mortality among both males and females.

In comparison with the previous year there is an increase in the death-rate at all ages during the year 1895, but this increase was particularly great under the age of five years. The mortality of infants under one year of age was extremely high. There were 4,663 deaths, being a mortality of 476·0 per 1,000, or a little below half of the infant population. The high mortality among infants is a prominent and discreditable feature of Calcutta, and urgently calls for improved sanitation in connection with the construction and cleanliness of dwellings and the proper regulation of the milk-supply, in addition to an improvement of the general drainage and cleanliness of the town. Though a good deal of any improvement in the health of the infant population will, in the long run, depend on the spread of sanitary education among the masses, and particularly among the female section of the community, a considerable part of it lies within the range of public hygiene; and this particularly applies to the laying down of proper rules and regulations for the construction of sanitary dwellings, and for the control of the milk-supply in Calcutta, to the removal of the defects in the general drainage, and to the adoption of proper means to secure an efficient daily cleansing of the town. The mortality of infants under one year of age was greater in urban than in suburban Calcutta, being 531·9 against 392·9 per 1,000 of infant population, and indicates in what part of the town improvements are more urgently required. It was slightly greater in females than in males, and it was, as usual, greatest among the Muhammadans, and least among the Christians.

The death-rates according to nationality were higher during 1895 than during 1894. The figures are 30·9 anong Christians, 39·0 among Muhammadans, 40·2 among Hindus, and 59·0 among Other Classes in 1895, against 23·5, 31·4, 34·0, and 48·7, respectively, in the previous year.

The main factors contributing to the increase in mortality in Calcutta during 1895 were an exceptional rise in fevers and small-pox, and an increase of cholera and bowel-complaints; and this statement applies to the town proper, the canal area, and the suburbs, both when taken separately and when they are considered as a combined area.

The large number of deaths registered under fevers during 1895 was one of the main causes of the high death-rate in the town. The total number of fever deaths recorded in urban and suburban Calcutta was 11,345, which is an increase of 2,382 deaths above the number registered in 1894. The figures for the town proper and the suburbs in the two years were—

Year.	Town proper.		Suburbs.		Total.	
1894 - -	5,712	12·2	3,251	15·1	8,963	13·1
1895 - -	6,831	14·6	4,514	20·9	11,345	16·6

From these it will be seen that in 1895 there were in the town 1,119, and in the suburbs 1,263, more deaths from fever than in 1894.

The number of deaths from fevers in urban Calcutta during 1895 was the highest on record, exceeding that of every year since 1865, the earliest year of which records are available. The rise in the fever deaths in urban Calcutta is not a sudden one peculiar to 1895, though this year is distinguished by recording a number of deaths which exceeds by 745 the maximum number recorded in any of the previous 30 years.

There has been a gradual steady increase during the past seven years, as shown by the following figures:—

Year.	No. of Deaths from Fevers.	Death-rate from Fevers per 1,000 of Population.	Year.	No. of Deaths from Fevers.	Death-rate from Fevers per 1,000 of Population.
1889 - -	3,341	7·7	1893 - -	4,749	10·1
1890 - -	4,154	8·9	1894 - -	5,712	12·2
1891 - -	4,675	10·0	1895 - -	6,831	14·6
1892 - -	4,632	9·9			

The annual death-rate from fevers in urban Calcutta exceeds that of the suburbs at the amalgamation, and shows every tendency to a further increase unless remedial measures be adopted in the meantime. It is known that scarcity of food is always followed by a rise in the fever ratio. The variations in the price of food, as indicated by the price of common rice, are shown side by side with the annual death-rates from fevers during the past 11 years in the following statement:—

Year.	Price of Common Rice.	Death-rate from Fevers.	Year.	Price of Common Rice.	Death-rate from Fevers.
	Rs. As. P.			Rs. As. P.	
1885 - -	3 5 4	8·8	1891 - -	3 8 9	10·0
1886 - -	2 8 0	7·8	1892 - -	4 6 0	9·9
1887 - -	3 2 0	7·5	1893 - -	4 10 0	10·1
1888 - -	3 4 4	7·3	1894 - -	4 9 4	12·2
1889 - -	3 5 0	7·7	1895 - -	3 12 0	14·6
1890 - -	3 2 0	8·9			

It will be seen that the variations in the price of food bear no proportion to the variations in death-rate from fevers, nor can any direct relation between the two be established in any other way. The connexion between the prevalence of fevers in urban Calcutta and the defective condition of its sewerage system, however, is more or less intimate, and indicates the direction in which remedial measures should be first directed.

As regards the suburban area, the naturally water-logged condition of its soil, rendered worse by the existence of numerous tanks and dobas the waste of water consequent on the introduction of water supply, and the want of drainage, is a sufficient explanation of its fever ratios, and clearly indicates the requirements.

Cholera.

The mortality from cholera was above the average of the previous six years. The number of deaths was 2,099 against 1,955, the hexennial mean, giving a death-rate of 3·0 against 2·9 per 1,000 of population. Of these, 1,302 deaths occurred in urban Calcutta, exceeding the mean of the previous 10 years by 18, and 797 deaths took place in suburban Calcutta, being lower than the average of the preceding six years by 64. The figures for the two areas are as follow:—

——	1885.	1886.	1887.	1888.	1889.	1890.	1891.	1892.	1893.	1894.	1895.
Town - - -	1,603	1,741	1,198	1,734	1,079	963	1,553	1,257	596	1,118	1,302
Suburbs - - -	—	—	—	—	1,236	916	1,402	762	273	577	797
Combined area - -	—	—	—	—	2,315	1,879	2,955	2,019	869	1,695	2,099

The mortality from cholera was greatest in Shampooker ward with a death-rate of 5·6 in its extended portion and 5·0 in its town portion, and it was lowest in Bamun Bustee ward, with a death-rate of 1·0, while the average ratio of 3·0 was attained in Jorasanko and Watgunge. Of the remaining wards, all the urban wards south of Machooa Bazar and Cotton Streets as well as the town area of Sukea's Street and suburban area of Moocheepara, and wards Baniapooker and Khidderpur had cholera ratios below the total ratio for the town, while the rest exceeded that ratio. Next to Shampooker, the wards Jorababan, Bhowanipur, Burtola, and Balligunge suffered most from cholera during the year 1895.

As in the previous year, the heaviest mortality was in March and April; and commencing from the latter month, a series of observations were made during the year to ascertain the distribution of *comma bacilli* in the water of the Hooghly river, the Tolly's Nullah and the Circular Canal and in the water of tanks and wells in Calcutta. 104 samples of water were collected and examined, of which 60 were from different points of the river Hooghly, 8 from the Tolly's Nullah, 5 from the Circular Canal, and 31 from tanks and wells. The results obtained may be thus summarised—

Of the water of the Hooghly *commas* were found in	12	samples,	or	20	per cent.
,, ,, Tolly's Nullah	,,	= 6	,,	75	,,
,, ,, Circular Canal	,,	= 2	,,	40	,,
,, ,, Tanks and wells	,,	=19	,,	61	,,

Attention was specially directed to the water of the river and the two canals in consequence of the fact that cholera was largely prevalent among persons who were in the habit of bathing in it or otherwise using it. The tanks, the water of which was examined, were situated in localities where cholera had taken place. The use of their water was at once prohibited, and guards were placed to prevent people from removing or using the water.

Small-pox.

There were 2,220 deaths from small-pox during the year 1895. Of these 1,687 occurred in urban Calcutta, 4 in the Port, and 529 in suburban Calcutta. These numbers are far above those of previous years except 1865. As has been stated in previous reports, small-pox prevails epidemically in Calcutta every fourth or fifth year, and lasts for two years more or less, with intervening years of almost complete freedom. In some epidemics the first year's prevalence is greater and severer than the second, while in others the reverse is the case. In the epidemic during the year under report, which commenced in the beginning of 1894, the latter has been the case. No year, however, passes without some cases. But in ordinary years the cases are single and isolated, and are mostly imported by infected people coming to Calcutta. In such years there is little tendency for the disease to spread, and in certain seasons of the year, especially during the very hot months and the rains, the infectious properties of the disease appear to be extremely slight. In the present state of our knowledge it is not possible to say what the cause or causes of this periodic accession and decadence in the prevalence of the disease are. This much is known, however, that successful vaccination and revaccination usually prevent the occurrence of the disease or modify its virulence.

The epidemic of small-pox in 1895 was a continuation of that which commenced with the beginning of 1894. The disease first appeared at Kalghât in January 1894, and gradually extended to the town and other parts of the amalgamated area. In April and May, 1894, the disease was at its height. In June it began to decline, and was finally stamped out in the suburbs. But in the town it smouldered on, notwithstanding every effort to stamp it out, and cases continued to occur throughout the year. This was a bad feature in the epidemic, and led to the apprehension that the disease would prevail to an unusual extent in the year under report (1895). In fact, from the end of December 1894, the disease assumed renewed vigour, and cases began to occur in large numbers in urban Calcutta and Tallah. These cases came to notice in the beginning of January 1895. To meet the increased demand for vaccination around the centres of contagion, two extra vaccinated calves were employed. But as the disease spread in urban Calcutta and also extended to the amalgamated area, and as from the advertisements issued by the Health Department, the demand for vaccination increased to an unusual extent, eight calves were employed daily, and a very large number of vaccinations and revaccinations were performed both at the stations and in infected localities, as well as in private houses. As the disease, however, continued unabated up to April, six extra Medical Inspectors, seven extra vaccinators, and one Inspector of vaccination were employed, and besides the daily supply of eight calves from which lymph was taken direct, prepared lanoline vaccine was used to vaccinate people in bustees in the vicinity of houses affected with small-pox.

Not only was vaccination vigorously pushed on in infected localities, but the Medical Inspectors promptly disinfected the houses of the small-pox cases, and destroyed the beddings and clothes of the patients. There are many difficulties that stand in the way of carrying out precautionary measures against the spread of the disease in Calcutta. *First*, there is great difficulty in obtaining prompt information of the occurrence of cases. The patients and their friends, particularly among the poorer classes, have a dread of small-pox hospital, and for fear of removal of the patients to hospital, abstain from giving intimation of the occurrence of cases to the sanitary

authorities. Moreover, small-pox cases being rarely attended or treated by ordinary medical practitioners, little assistance is available from that source in the early detection of cases. *Secondly*, the isolation of patients is in many instances difficult or impracticable. The law allows only poor and practically houseless *male* patients to be removed to hospital against their will; and even in the case of such patients removal to hospital, before they have had time to spread the contagion, is frequently impossible in consequence of their friends and acquaintances keeping the occurrence of the cases as secret as they can. The law gives no power to the sanitary authorities to isolate females and infants by removal to hospital; and infants under five years of age were the greatest sufferers from small-pox during 1895.

From May the disease began to decline, and although isolated cases continued to occur in some of the wards of the town and amalgamated area in June, July, and August, it died out altogether in September. From October to December there was not a single case of the disease among the residents of Calcutta, though the following cases were imported into the town and admitted in the Small-pox Hospital at Sealdah, viz., on the 14th November, 1895, *S. S. Dalhousie* arrived at Khidderpur with a small-pox case on board. On the 2nd December a cooly recruit arrived at 21, Garden Reach Emigration Depôt, From Fyzabad, and got small-pox immediately after arrival, and was removed to Sealdah Hospital on the 16th December; and two cases were imported from Kashipur, a village on the south of Taratola Road, very close to, but not within the jurisdiction of Calcutta. But the epidemic tendency of the disease being over, these cases did not lead to the spread of small-pox in the town.

Of the 2,220 deaths that occurred in 1895, 420 were reported as inoculated, 501 as vaccinated, 3 as previously having had small-pox, and 1,217 as unprotected, that is, as persons who had never been vaccinated or inoculated, nor had had natural small-pox.

Dysentery and diarrhœa.

The mortality from dysentery and diarrhœa was considerably higher than that of any year since 1889. There were 3,269 deaths from this cause against 3,136 in 1894, and against 2,769, the mean of the six years 1889 to 1894. Of these 1,599 deaths occurred in urban Calcutta, exceeding all the corresponding figures of the preceding decade except 1885, and 1,670 deaths took place in suburban Calcutta, which is considerably in excess of the corresponding figures of the previous six years.

Other causes.

The mortality from all other causes in 1895 was lower than that of the previous six years except 1890 and 1891, and fell below the hexennial mean by 83. There were 8,098 deaths against 8,242 in 1894, being a mortality of 11·9 against 12·0.

Vaccination.

Vaccination against small-pox was carried on vigorously during the year 1895, and particularly during the first five months when there was an unusual prevalence of small-pox in Calcutta. The total number vaccinated during the year 1895 amounted to 54,982. Of these 15,184 were cases of primary vaccination and 39,798 of re-vaccination. The corresponding figures of the previous year were 10,638 and 10,398, respectively. This shows an increase of 4,546 primary and 29,400 re-vaccinations. Of the 15,184 primary vaccinations, 13,506 or 88·88 per cent. were successful, 709 or 4·66 per cent. were unsuccessful, and in 969 or 6·31 per cent. of cases the result was not ascertained. In primary vaccinations the rate of success calculated on the ascertained cases was 95·0 per cent. Of the 39,798 re-vaccinations, 4,080 or 10·25 per cent. were successful, 26,384 or 66·29 per cent. were unsuccessful, and in 9,334 or 23·45 per cent., the result was not ascertained. The rate of success on ascertained cases in re-vaccinations was 13·32. Of the total number re-vaccinated, 38,218 were males and 16,764 were females. According to nationality, 9,503 were Christians, 33,068 were Hindus, 12,147 were Muhammadans, and 264 other castes; 5,253 were under one year of age, 10,765 were one year and under six years, and 38,964 were six years and upwards.

Vaccination was systematically carried on in all sections of the town and amalgamated area during the year. In Calcutta both the humanised and animal *virus* was kept up by regular transmission and used all the year round. The demand for animal *virus*, however, is increasing every year. Even the lower classes often prefer the calf lymph, and the Marwarees in some cases have allowed their children to be vaccinated from the calf. The prejudice against the use of calf lymph is gradually dying out. During the hot months, such as May and June, calf lymph deteriorated, and all vaccinations performed proved unsuccessful. Fortunately, there were very few

primary vaccinations required at the time. Virus was imported from Darjeeling and Bombay to replenish the lymph, but without success. The Deputy Superintendent of Vaccination, however, procured humanised lymph from the Inspector of Vaccination of Howrah in capillary tubes and established a *virus* in Calcutta by vaccinating children with it, and the lymph thus obtained was then transferred to calf, the vaccine from which proved successful.

ABSTRACT OF REPORT OF THE MADRAS MUNICIPALITY FOR 1895-96.

(*Lieutenant-Colonel G. M. J. Moore, C.I.E., President.*)

Drainage.—During the official year Rs. 52,333 have been spent under this head, the principal work being laying a sewer from Thacker Street to DeMellows Road pumping station *viâ* Perambore Barracks Road, thus dispensing with the Picottahs at Angalammen Covil Road, Astabujam Road, and Strachans Road, and effectually removing the sewage which used to stagnate at these places. The question of carrying out a comprehensive scheme for the drainage of the whole town is still under the consideration of the Committee, and a trial sewer is to be laid in Parish Vencatachella Iyer Street in order to ascertain the best method of connecting the house drains with the sewer. No great reduction in the mortality of the town can be expected until a good system of drainage and sewerage has been carried out. Government have been pleased to grant Rs. 3,50,000 towards the drainage of Madras and it is hoped that some progress will be made during the next year.

Water-supply.—The Hydraulic Survey of the town referred to in paragraph 185, Section II. of last year's report was completed by the engineer. A sum of Rs. 474,498 has been expended on new works and repairs. Two auxiliary mains have been laid from Kilpauk, one through the 6th and 8th Divisions and the other through the 4th and 1st Divisions, whereby the supply in those portions of the town which were very defective has been greatly improved. The supply is still cut off once a week for the purpose of cleaning the masonry shaft, and though the supply has been considerably improved as regards the quantity, no steps have yet been taken to improve the quality. The analysis of water is anything but satisfactory.

Vaccination.

During the year 1895–96 the total number of cases vaccinated was 27,024 against 24,725 in 1894–95 showing an increase of 2,299 cases. The increase was due to the large number of re-vaccinations performed on adults employed in the various office establishments, firms, &c., in consequence of the prevalence of small-pox in the city in the latter part of the year under report. Out of 27,024 cases vaccinated 16,080 were males and 10,944 females. 25,108 were successful, 804 unsuccessful, and 1,112 unknown. The unsuccessful and unknown results were greater than in 1894–95 by 316 and 184 respectively. The former was due to the large number of re-vaccinations and the latter to convicts. Civil prisoners of the Debtor's Jail, emigrant coolies, &c., having been released before the result of the operation could be ascertained. During the year 1895–96, 2,016 cases voluntarily resorted to the depôts for inspection of the result of the operation. The vaccinators of the respective divisions verified 20,945 cases under Byelaw 11, and issued "successful certificates" to the parents and guardians. These results were again inspected by the Deputy Inspector and four Assistant Deputy Inspectors. The results of vaccination among the convicts of the Penitentiary, civil prisoners of the Debtor's Jail, the emigrant coolies of the Natal and Mauritius Depôts were examined by the Deputy Inspector. More than 50 per cent. of the total number of cases vaccinated were examined by these officers.

The accompanying statement shows the number of cases vaccinated during 1895–96 as compared with 1894–95. As usual calves were sent out to the Natal Emigration Depôt and 2,193 coolies were re-vaccinated against 2,165 in 1894–95. Calves were also sent to the Penitentiary thrice a week to vaccinate the convicts undergoing short terms of imprisonment of from three to five days. The civil prisoners of the Debtor's Jail were sent to the Monegar Choultry Vaccine Depôt and the coolies of the Mauritius Depôt to the Tondiarpet Vaccine Depôt. The number of cases vaccinated in the Penitentiary during 1895–96 was 1,948 against 1,887 in 1894–95. Under the provisions of the Jail Code every convict was hitherto vaccinated on admission, but this rule has been modified during the year thus, "provided that prisoners "who on admission show clear marks of recent successful vaccination need not "be re-vaccinated. Thus, prisoners who have been successfully vaccinated while

" temporarily detained in sub-jails need not be re-vaccinated on admission to Central " and District Jails."

Year.	Total vaccinated.	Compared with the preceding Year.		Successfully vaccinated.	Percentage of success, excluding the unknown cases.
		Increase.	Decrease.		
1894-95 - -	24,725	1,081	—	23,309	97·94
1895-96 - -	27,024	2,299	—	25,108	96·89

The percentage of success in primary and re-vaccinations, excluding the unknown cases from the total, was 96·89 against 97·94 in 1894-95, showing a decrease of 1·5 per cent. due to the large number of re-vaccinations performed during the year 1895-96. The tri-weekly vaccination system introduced in the year 1889-90 compares favourably with the daily vaccination performed in the previous years.

During the year there were nine Vaccine Depôts in which vaccination was carried on free of charge. In seven of them work was carried on tri-weekly, in one (Thousand Lights) tri-weekly, and in one (Egmore) weekly. Calves are inoculated in the Central Depôt, Chintadripet, and sent to the various depôts on working days. During the year, 90 inoculated calves and 391 tubes of lymph were sent on applications to vaccinate persons in private houses. 149 calves were sent to the Penitentiary to vaccinate the convicts, and 44 calves to the Natal Emigration Depôt to vaccinate the coolies.

Out of 27,024 cases vaccinated 2,122 were Europeans, East Indians and Native Christians, 2,464 Muhammadans, 22,298 Hindus and 140 other castes. Out of a total of 27,024 cases operated on 18,877 were primary vaccinations, showing a decrease of 534 cases when compared with the previous year. Of the primary vaccinations, 18,598, or 99·66 per cent. were successful, showing a slight increase of ·3 per cent. over the year 1894-95. There were 8,147 cases of re-vaccination performed on adults with 89·76 per cent. of success against 5,314 with 91·0 in 1894-95, showing a fall of 1·24 per cent. though there was an increase of 2,833 operations.

The number of infants vaccinated during the year was 13,187 against 13,414 in 1894-95, showing a small decrease of 227 cases. Of these, 13,027, or 99·74, were successful. The following table shows the number of cases vaccinated during the past three years under different ages. Out of 27,024 cases 13,187 were infants under one year, 5,019 were above one and under six years, and 8,818 cases above six years :—

	Total Number Vaccinated.			Ratio per Cent. of the Total Number Vaccinated.		
	1893-94.	1894-95.	1895-96.	1893-94.	1894-95.	1895-96.
Under one year - - -	13,343	13,414	13,187	56·4	54·3	48·8
Above one and under six years -	5,021	5,420	5,019	21·3	21·9	18·6
Above six years - - -	5,280	5,891	8,818	22·3	23·8	32·6
Total - - -	23,644	24,725	27,024	100·0	100·0	100·0

Vital statistics.

Births.—During the year 1895 the total number of births registered was 19,137, exclusive of still-births, being 2,075 more than in the previous year, and the highest number recorded in the decennium. The increase in births took place in the second half of the year and was due to food having become appreciably cheaper during the year 1894 and remaining more or less stationery during the year under report. Of these births, 9,767 were males and 9,370 females, the proportion being 104·2 to 100. The number of still-births was 513 against 541 in the previous year. Of these 276 were males and 237 females, the proportion being 116·4 to 100.

The Muhammadans were the most prolific, their birth-rate being 45·1, which shows an increase on previous years. The Hindus came second with a ratio of 42·2, and the Christians third with 39·1. An increase of birth-rate took place amongst all the castes.

Mortality.—The deaths registered during the year numbered 17,052 against 16,542 in 1894, being in the proportion of 37·6 per 1,000 against 36·5 last year, the mean of

the decade being 38·7. The slight increase in the death-rate was partly due to the increase in birth-rate. The ratio in Calcutta for the year under report was 39·6 per 1,000. The months of August and September showed the highest death-rate, viz., 52·6 and 51·2.

The price of food.—During the year there was not any appreciable change in the price of rice as compared with that of last year. Ragi, however, was much cheaper than it was in the previous year.

Mortality from different diseases.—A comparison of the relative mortality from different diseases in 1894 and 1895 shows that the deaths registered under small-pox were fewer in the year under review, and those under all other diseases were more numerous. The death-rate from fevers was above the decennial average, all the others being below. The mortality from small-pox was the lowest except in 1886, when only one death occurred.

Statement of Mortality from the Prevalent Diseases in 1895 *contrasted with that of* 1894.

Years.	Small-pox.	Measles.	Fevers.	Dysentery and Diarrhœa.	Cholera.	Total.	Other Causes.	General Total.	Ratio per 1,000.
1894 - - -	12	190	6,128	2,392	77	8,799	7,743	16,542	36·5
1895 - -	3	249	6,265	2,204	122	8,843	8,209	17,052	37·6
Average for 10 previous years.	32·4	387·0	5,002·0	3,020·0	481·8	8,923·2	8,608·4	17,531·6	38·7

Out of a total mortality of 17,052, 8,509 were males and 8,543 females, giving the proportion of 99·6 to 100. If the death-rates are compared with those of the previous year, it will be found that the increase in the rate among Muhammadans was greatest, the Christians coming next and the Hindus being last. The increase in the death-rate was 2·8, 2·4, and ·8 per 1,000 respectively. The number of deaths according to caste for the year was Hindus, 13,615, Muhammadans, 2,150, Christians, 1,284, the ratios per 1,000 being 37·9, 40·4, and 32·3.

Small-pox.—During the year 1895 the number of deaths from this disease was 3, being the smallest on record except in 1886, when only one death occurred. All three were hospital cases, the residence of two being given as Black Town and the other unknown. All were males and were above the age of 20; this result is due to the excellent work done by the staff of the Vaccination Department.

Cholera.—During the year 122 deaths from cholera occurred against 77 in the previous year. Eighty-two deaths were registered during the first quarter; of these 68 occurred in January. The increase in the number of deaths over the previous quarter was owing to the outbreak of cholera in the Government Lunatic Asylum at the close of the previous quarter, and to the occurrence of some fresh cases in and near Perambore Cheklipalliam. In the 2nd quarter there were three deaths against two in the corresponding quarter of the previous year. The outbreak in the 3rd quarter commenced in the week ending the 28th June. There were 48 attacks and 36 deaths against none in the corresponding quarter of the previous year. Of these 14 deaths occurred in the 1st Division and 10 in the 3rd. In the 4th quarter there was only one death against 40 in the corresponding quarter of the previous year, the decennial average being 111·3.

Measles.—The deaths registered under measles numbered 249 against 190 in 1894, the average for the ten previous years being 387. The 5th, 7th, and 1st Divisions returned the largest number of deaths.

Fevers.—The deaths from fevers numbered 6,265 or 13·8 per 1,000, against 6,128 or 13·5 per 1,000 in the preceding year. The mortality was highest in the 1st Division, Centre Ward, which had a ratio of 19·4 per 1,000, and lowest in 8th Division, South Ward, being 6·7 per 1,000. Taking the divisions into consideration the highest mortality was in the 3rd Division, the ratio being 16·2 per 1,000, the 1st Division coming second with 16·1, and the 2nd Division coming next with 16. The largest number of deaths occurred in August and September, being 696 and 769 respectively, and the smallest in February, being 374.

Bowel complaints.—The deaths from dysentery and diarrhœa numbered 2,204, against 2,392 in the preceding year, being 1,536 from the former and 668 from the latter, which give the ratios 3·3 and 1·4 per 1,000 respectively, or 4·7 from the two together. Dysentery was most severe in the 1st Division, Centre Ward, and diarrhœa in 6th Division, South Ward.

ABSTRACT OF REPORT OF THE ACTING MUNICIPAL COMMISSIONER OF THE CITY OF BOMBAY FOR 1895-96.

(*Mr. P. C. H. Snow.*)

Public works.

SPECIAL DRAINAGE.—For the purpose of carrying out the various large schemes of special drainage required in the city, Mr. James W. Smith, M.I.C.E., the Drainage Engineer of the Municipality of Bombay, was appointed to be in charge of these works under the designation of Special Drainage Engineer, with effect from the 1st March 1893, and continued to hold that office throughout the year under report.

The unfinished works in progress, and the new works sanctioned or commenced during the year, were as follows:—

Colaba Sewerage Works.
Umarkhadi Sewerage Works.
Connaught Road and Sussex Road Drainage and Sewerage Works.
Parel Sewerage Works.
Mazagon Sewerage Works.
Malabar Hill and Khambala Hill Sewerage Works.
Fergusson Road and Chinchpokli Sewerage Works (gravitation portion).
Old Race Course Sewerage Works (gravitation portion).

Colaba Sewerage Works.—The original grant sanctioned for these works was Rs. 7,09,608, but, in addition thereto, the sum of Rs. 50,000 was sanctioned by the Corporation, bringing the total grant up to Rs, 7,59,608. At the close of the year the several payments made amounted to Rs. 7,53,198. The works are being constructed on the Shone system, which is composed of the application of two forces, one resulting from the compression of atmospheric air and the other the natural force of gravity.

Umarkhadi Sewerage Works.—The contractors for this part of the general scheme having withdrawn under notice from the work, it was carried on departmentally until stopped by the S.W. monsoon of 1895. Subsequently it was considered desirable to complete the work by contract. Tenders were therefore invited and work commenced on the 6th November. The total expenditure on the Umarkhadi Works up to the end of the year was Rs. 2,14,682.

Connaught Road and Sussex Road Drainage and Sewerage Works.—This work, so far as the contractors were concerned, is finished and paid for, but some portions yet remain, the completion of which cannot be effected until certain houses which will carry the vent-shafts have been built, and water can be laid on to the flushing tanks by a main.

Parel Sewerage Works (gravitation portion).—The contractors for these works did not complete them within the contracted period of six months, which expired on the 31st May 1895, but they were practically finished at the end of December. The final bill, however, cannot be passed until certain defects are remedied. The estimated cost of the work was Rs. 70,974, and the total expenditure at the close of the year was Rs. 58,127.

Mazagon Sewerage Works (gravitation portion).—The Corporation sanctioned the execution of these works at an estimated cost of Rs. 3,32,661. Tenders were accordingly invited and three were received. The work was commenced on the 23rd November 1895. The contract has to be completed in two years from that date. The total expenditure passed up to the end of the year was Rs. 46,479.

Malabar Hill and Khamballa Hill Sewerage Works (gravitation portion).—Sanction of the Corporation was accorded to carrying out this work at a cost of Rs. 1,57,026: Work was commenced on the 30th November 1895. The contract time for completion is 18 months. The expenditure passed up to the close of the year was Rs. 34,219.

Fergusson Road and Chinchpokli Sewerage Works (gravitation portion).—The total cost of this work is estimated at Rs. 93,572, but as the monsoon was approaching the work was allowed to stand over until the fine weather. No tenders had been invited at the close of the year.

Old Race Course Sewerage Works (gravitation portion).—The commencement of this work, sanctioned at a cost of Rs. 40,815, was also postponed until the fair season.

DRAINAGE.—*Pumping Station, Love Grove, Worli.*—The Worthington triple expansion pumping engines continue to give satisfaction, the average efficiency being 94 per cent. for the year. The whole of the plant was taken over from the makers in the month of May 1895, the last instalment of 2,396*l.* paid, and all claims were finally disposed of. Breakages of parts of the machinery occur occasionally, but the efficiency of the station is not interfered with, as three engines being sufficient for pumping purposes the fourth is always ready for use when wanted.

Colaba Air-compressor Station (Shone System).—The air-compressing machinery of the station consists of three compound non-condensing horizontal steam engines with air-compressing cylinders and a suitable receiver for containing the compressed air, steam being supplied by two steam boilers of the marine type, working up to a pressure of 120 lbs. per square inch. There are five ejector stations situated below the ground at different parts of Colaba, and in each station are two ejectors which, being actuated by the compressed air conveyed from the compressor station through pipes, cause the sewage to be propelled along suitable closed channels to its destination. The ejectors are automatic in their action. The work at the compressor station was practically completed in the beginning of July 1895, and the official trials proving satisfactory the plant was taken over on that date, and on the 22nd of August the station was formally opened, but regular work was not commenced until the 12th of December, since which date the system has worked satisfactorily. As only a few drainage connections have yet been made, the cost of raising sewage by this system has not yet been ascertained.

House Connections.—The Municipal Corporation, under their No. 12429, resolved, on the 29th January 1896, that "having had a favourable experience of the operation " of its resolution of 3rd November 1882, extending over a period of 13 (thirteen) " years, and having applied the principle embraced in the resolution to various " districts of the city with satisfactory results, and finding that the principle is in " complete accordance with the wishes of all the persons concerned, the Corporation still " adheres to that resolution, including in its scope all houses and outhouses, and all " new houses which were formerly excluded, and is now of opinion that the terms of " the resolution of the 3rd November 1882 as now amended should be made applicable, " in the future, to all the districts of the City." An advance of one lakh of rupees was provided and the house connection work of all new houses completed was undertaken, together with repairs to the connections of houses already connected by the municipality, and was carried out up to the end of the year. No expenditure on this account was debited to the above grant of rupees one lakh up to the 31st March 1896, as the expenses were incurred in March 1896.

The report of the House Connections Committee was submitted to the Corporation on the 10th December 1894, and the Corporation, at their meeting held on the 6th May 1895, resolved "that, in carrying out house connections in future the " Corporation trust that the recommendations of the Committee will be carefully " considered."

Waterworks, Tansa Lake.—The rainfall for the year 1895 was 92·37 inches. The heaviest rainfall in one day occurred on the 20th June 1895, when 5·34 inches were registered. The lowest water level was 394·85 T.H.D. on the 18th June. The lake overflowed on the 18th July after 31·59 inches of rain had been registered, and ceased to do so on the 3rd October. The quantity of water which passed over the waste-water weir is estimated at 18,735 millions gallons. The approximate quantity of water drawn off into the duct of the lake was 8,780,844,233 gallons throughout the year, of which quantity about 88 millions of gallons were passed into the Vehar Lake, the remainder being sent forward to the city. The building of inspector's quarters at Kaling, sanctioned by the Corporation at an estimated cost of Rs. 3,932, was in progress at the end of the year. The erection of chawls at the lake, at an estimated cost of Rs. 12,000, was also in hand at the close of the year. The supply of water from Tansa was shut off from the 30th November to 7th December to allow of the general inspection and repair of the duct. Two bursts of the 41 inches main occurred, but were soon repaired, the stoppage of water through this cause lasting only for a period of two days and 23½ hours. The second portion of the work of repairing and strengthening the Kasheli embankment was in progress at the end of the year. The grant for the whole of this work was Rs. 30,000. The expenditure on the part previously done, inclusive of that in progress, was Rs. 26,212.

Vehar Lake.—The rainfall for 1895 was 82·81 inches, being 2·75 inches less than in 1894, and 1·09 inches less than the average, which is 83·90 inches. The lake over-

flowed on the 12th August, and ceased on the 26th September. The heaviest rainfall in one day was 8·30 inches on the 8th September. The lowest water level was 253·70 T.H.D. on the 14th June. The storage on the 31st October 1894 was 11,335 millions of gallons, and on the 31st October 1895 was 11,010 millions of gallons. The daily loss during the dry season from 31st October 1894 to 31st May 1895 was 14·3 millions of gallons per day, in addition to that drawn from Tansa Lake. The estimated quantity of water received into the Vehar Lake from the Tansa Duct between the 31st October 1894 and the 31st May 1895 was 82·5 millions of gallons. Between the 8th August and 17th September 1895, 581 millions of gallons were received from the Tulsi Lake by overflow. The quantity of water that passed over the Vehar waste weir between the 12th August and the 26th September was estimated at 4,191 millions of gallons; a joint leak occurred at Chinchpookly, and a burst on the Suparibaug Road.

Tulsi Lake—The rainfall for the year 1895 was 100·40 inches. The heaviest fall in one day was 8·08 inches on the 8th September. The lowest water level was 439·50 T.H.D. on the 14th June. The lake overflowed on the 8th August, and ceased to do so on the 17th September 1895. The storage on the 31st October 1894 was 2,243 millions of gallons, and on the 31st October 1895 it was 2,136 millions of gallons. The loss during the dry season from 1st November 1895 to the 31st March 1896 was 880 millions of gallons. The quantity of water which passed over the waste weir into the Vehar Valley is estimated at 581 millions of gallons.

Pawai Lake.—The water-supply from this lake was not required throughout the year. The pumping plant was transferred from the water branch to the Assistant Executive Engineer, Mechanical Branch, with all accessories thereto, on the 29th January 1896. After protracted proceedings in the Thana District Court and the Bombay High Court, the purchase-money for the land acquired for the Pawai works, amounting to the total of Rs. 1,67,904, was paid into Court.

Malabar Hill Reservoir.—The Corporation, as per their Resolution No. 12569 of 30th January 1896, sanctioned certain structural alterations to the filters at the Malabar Hill Reservoir at a cost of Rs. 14,400, and the work was in progress at the close of the year.

Bhandarwada Reservoir.—The filters have worked satisfactorily throughout the year. The covering of the clear water channel has answered its purpose. The parapet wall between the filters and distributing basin was raised at a cost of Rs. 434; this was to prevent the filtered water being fouled by washings from the garden over the distributing basin. The work of covering the storage basin was proceeded with throughout the year, but was not completed at the close of the year. The original grant for this work was Rs. 1,60,097, but the revised estimate shows that it may be completed for Rs. 1,47,000, whereby a saving may be realised of Rs. 13,097. The filling up of filter No. 9 with filtering materials was commenced, and photographs were taken at intervals of about three months, to show the progress and character of the work.

During the year the offers of reward for the capture of crocodiles in the lakes, and the finding of their eggs, resulted in claims for 7 crocodiles and 91 eggs. There was one reported case of leeches being ejected from the service tap of a house in the Fort. This being traced, was found to be most likely due to a broken service pipe near a drain in which many leeches were found.

Distribution and Maintenance.—The number of bursts of water mains throughout the year was 255, against 313 during last year. During the year 522 new connections were made, and 243 services disconnected on account of buildings demolished, non-payment of rates, or for infringements of the provisions of the Municipal Act. The net increase in the number of connections was 279, bringing the total up to 19,455, and showing an increase of 1·4 per cent. The meters in use on the 31st March 1896 numbered 1,854, being an increase of 180 over the previous year. The registered consumption, as per meter, throughout the year, was 1,290,500,000 gallons. The night reading work to check waste has been considerably increased owing to disturbance of sub-soil for drainage work.

Public health.

The state of the public health during the year under review showed a great improvement over that of the previous year, there being a decrease in the mortality of 2,249. The total number of deaths from all causes amounted to 25,081, equal to a death-rate of 30·52 per 1,000 of population calculated on a population of 821,764 (census of 1891). The average number of deaths for the previous five years amounted to 25,183, or a death-rate of 30·64 per 1,000 of population. The mortality returns show a decrease in almost all the usual causes of death.

The number of deaths according to place of birth was as follows :—

Born in Bombay - - - -	11,584
Born elsewhere and unknown - - -	13,497
Total - - -	25,081

The sections of highest mortality were 2nd Nagpada 50·61, Kamatipura 44·85, Tardeo 40·62, Khara Talao 39·24, Oomarkhadi 36·51, Chukla 36·49, Byculla 36·11, Girgaum 35·85, and the sections of lowest mortality were the Water Division 3·02, Fort Southern 8·60, Esplanade 12·51, Chowpati 14·76, Walkeshwar 16·32, and Mahalakshmi 18·39, per 1,000 of population. The death-rate was highest amongst Negro-Africans, Lingaets, Hindu low caste, Jains, Mussulman, Bhatias and Eurasians, being 541·09, 65·05, 47·22, 45·15, 39·30, 38·27, and 35·56 per 1,000 of population respectively, and lowest amongst Europeans, Parsees, Jews, Native Christians, and Brahmins, being 20·81, 22·94, 23·70, 25·51, and 25·72 per 1,000 of population respectively.

Cholera.—The number of deaths from cholera was 90, or 336 less than in the last year, and 112 below the average. The sections of greatest mortality were Parel, Mahim, Tardeo, Mahalakshmi, Tarwadi, Byculla, and Mandvie. The highest mortality by class was amongst Eurasians, Hindu low caste, Hindus of other castes, Bhatias, and Native Christians.

Small-pox.—The deaths from small-pox were 270, or 261 below the total of the previous year, and 36 less than the average. They occurred chiefly amongst the Negro-Africans, Lingaets, Native Christians, Brahmins, and Jains. The mortality was highest in Girgaum, Fanaswadi, Middle and Lower Colaba, Dhobi Talao, Parel, and Mazagon.

Measles.—There were 544 deaths from measles, or 243 less than in the previous year, and 28 more than the average. Of these, 423 occurred in the first three years of life. The highest mortality occurred amongst Lingaets, Hindu low caste, Jews, and Eurasians. The death-rate was highest in the districts of Dongri, Girgaum, Kamatipura, Oomarkhari, and Tardeo.

Fever.—There were 6,404 deaths from fevers, or 54 less than in the previous year, and 272 less than the average. The death-rate was highest in the districts of Sewri, Khara Talao, Mandvi, Chukla, Girgaum, Mazagon, and Dongri. The greatest mortality was amongst Negro-Africans, Lingaets, Jains, Bhatias, Hindu low caste and Brahmins.

Leprosy.—There were 42 deaths from Leprosy, or 9 less than in the previous year, and 17 below the average.

Births.—The number of births registered, exclusive of still-born, was 15,684, or 626 more than in the previous year. Of these, 8,150 were males and 7,534 females. Excluding Negro-Africans, the birth-rate was highest amongst Hindu low caste, Jews, Parsees, Lingaets, and Eurasians. The sections giving the highest birth-rate were Mahim, Parel, Tardeo, Kamatipura, Chukla, and Sion.

Conservancy.—On an average 4,419·4 men and women and 1,092·51 scavengering and drain carts, and 205 night-soil and cess-pool carts were at work each day. 322,656·69 tons of garbage, equal to 883·99 tons a day, was collected and removed and disposed of, against 321,991·91 tons in 1894. 149,670·62 tons of night-soil equal to 410·05 tons a day, was collected and removed, against 150,004·24 in 1894. 179·6 miles of covered drains were opened and cleaned, against 182·3 in 1894. There were 5 horses and 2,231 bullocks owned by the Municipality, and of these 2 horses and 199 bullocks died and 40 were cast off and sent to the Pinjrapole.

ABSTRACT OF REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1896.

(Surgeon-Lieutenant-Colonel T. S. Weir.)

Although there has been a very great improvement in the public health this year, the mortality being 2,249 less than in the last year, yet I cannot hope for further reduction in the mortality until the local insanitary causes that I have so frequently described, and which I will once more describe so that there may be no responsibility on me, are removed. 25,081 deaths were registered, being 2,249 less than in 1894. Of this reduction in mortality 820 deaths were from diseases of the respiratory system, 594 from diseases of the digestive system, 336 from cholera, 261 from small-pox, 243 from measles, and 54 from fevers.

The two previous years 1893 and 1894 were remarkable from the meteorological phenomena observed and the incidence of diseases recorded, not only amongst human beings, but amongst animals. The abnormal meteorological features of these two years were accompanied by the prevalence of zymotic diseases amongst human beings and animals.

I have in former reports again and again demonstrated that epidemic states amongst animals or human beings in the city have always been synchronous with epidemic conditions and influences in the country around. The experience of this year is a further confirmation of the accuracy of this opinion.

In the report for 1893 I wrote as follows :—"I have after the very unfavourable "record of 1892 to report in this year a very great improvement in the public health, "the mortality being 3,376 less than in that year, but only 197 less than the "average. This is so far satisfactory, but it will not and cannot continue unless "that more effective means for carrying away the water brought into the city are "constructed."

Although in 1895 there have been 2,249 fewer deaths than in 1894, I must repeat again what I wrote in 1893, that this improvement in the public health, so far as represented by 2,249 deaths, will not and cannot continue unless that more general and therefore more effective means are constructed for carrying away the water brought into the city. It is true that the reduction in mortality over the previous year indicates that the general health of the city was so much better, but it does not indicate, when the figures are carefully examined, that the local causes of disease have been proportionately removed. The reduction is chiefly due to a lower mortality from diseases whose prevalence I have always contended was due, not to local conditions, but to general seasonal influences, although the mortality from each type of disease was influenced and intensified by local conditions. The reduction in mortality due to fevers is not considerable, being 54 less than in the last year and 273 below the average. The chief reduction has been caused through a diminished mortality from cholera, small-pox, and measles, or, in other words, the three chief zymotic causes and the groups of diseases which accompany or are synchronous with them. I will now briefly discuss the local causes unfavourably influencing the public health, and in doing so I am merely repeating the remarks made in previous reports, and more especially in the Quarterly Reports of the last year, and in the last Annual Report. The causes are :—

I. Insufficient drainage—
   - *a.* Sewage.
   - *b.* Subsoil water.
   - *c.* Absence of connections between building and sewers.

II. Over-crowding.

III. Disposal of all the dry refuse on the flats.

IV. The imperfect provision in the Municipal Act in regard to—
   - *a.* Rebuilding of houses on old foundations without a space for ventilation and drainage being left on one side.
   - *b.* The exclusion of the evidence of municipal officers in regard to nuisances.

V. The obstruction of the sea-currents around the Island by the embankments at Bandora and Coorla.

The unequal equilibrium between the water coming into the island and the liquid sewage pumped out is the most serious and urgent condition affecting the public health to be given attention to.

There has been an enormous increase of the water supply since 1892, from 16½ million gallons to some 29 million gallons or more daily, and very little increase in the number of drains. The island is flooded or irrigated with water, and unless drains are constructed to take away all the water that comes into the city, the life of a healthy population will not be possible; what has been seen in countries of marsh and wet, the poisoning of life from malarial fevers, will be seen here. It is not possible to look to the future except with anxiety. With incomplete drainage, there has been an enormous quantity of water left in the ground, some five or more million gallons of water daily, which the pumping power has been unable to remove, a floating balance indicating danger; and there must be, however powerful and perfect the pumping power may be, an enormous quantity of water which will not flow away and which cannot flow to, nor be carried by, the tributary drains of the out-fall sewer, till drainage channels are constructed, because in more than half the island there are not drains. I hope much in the future from the new and powerful pumps and the increased pumping power which it is known they give, but drains must be constructed in the districts undrained to carry the water and sewage to the tributaries of the pumps, if the greater power in pumping is to have any general effect in reducing the balance of water now unremoved in the island. However powerful the pumps may be, there must be drains in the districts which now have not drains, if the pumps are to remove the water and the drainage from these districts. The first principle for the preservation of public health is this, that the water coming into the city shall be taken away and not left in the soil, and this first principle has been neglected so far in Bombay. Even the water currents round the island have been obstructed by the causeways and embankments at Bandora and Coorla. The estuary between Bombay, Bandora, and Coorla is silting up. The most offensive trades, the tanneries, discharge into the estuary, and the water at low tide is fœtid.

The obstruction of the sea-currents around the island by the embankments at Bandora and Coorla or elsewhere is, next to insufficient drainage on land, the most serious condition affecting generally the island. An additional water-way ought to be opened on the south side of the Dharavie Creek so as to establish a current on the south to scour away the drainage from the tanneries. To those who take an interest in the public health few questions can be of more interest than the state of the subsoil water of the island.

There is no doubt the questions of first importance to the health of this city are: (i) the completion of the drainage of the city, and (ii) the prevention of waste of water. The drainage operations have given us an opportunity that we had not before of observing the distribution of the subsoil water. If anyone had a doubt as to the saturation of the subsoil and as to the rapidity with which the subsoil water, in some portions of the island, rises and falls, an inspection of some of the drainage excavations near Colaba would dispel that doubt. The rapidity with which the subsoil water rises in portions of Colaba, is the most extraordinary phenomenon that can be observed in this island; it is a phenomenon which can be observed with the eyes, for in some of the excavations as soon as the subsoil water has been pumped out, fresh subsoil water can be seen welling up. It seems as if the tidal currents flow across under the land, and the loose nature of the artificial soil of portions of Colaba which have been reclaimed favour the circulation of the currents. The drainage works have also given us an opportunity of studying the distribution of the subsoil water in other portions of the island as, for instance, on the north side of the Marine Lines, where some 1,008,000 gallons of subsoil water were pumped out between the 5th and 25th February 1896. In Oomerkharee I observed a curious and interesting phenomenon showing how in rocky formations houses may be damp on the sides of the drainage excavations. Between the rock formation and the road metal there seemed to be a reservoir of subsoil water which kept escaping into the excavations. The drainage works in one portion of the city, near the Cawasji Patel Tank, have also come down to what can only be described as an underground stream. It has to be remembered that the position where this stream has been struck is near Howdachi Wadi, from wells in which, at one period, a portion of the water-supply of Bombay used to be pumped up to the two tanks. An enormous quantity of water has been pumped up from this excavation and the stream seems as free as ever. My impression is that the excavation there has struck the subsoil stream that fed the Baboola tank and the wells in Howdachi Wadi, for there has been this year a very remarkable subsidence in the

level of the water in the Babula tank. The water in this tank has never been so low before; even when, many years ago, the municipality attempted to clean the tank out, it was not possible to pump the water to as low a level as it has fallen this year. The low level of the water disclosed two large streams of subsoil water entering the tank from the south. I may mention that on a former occasion when it was attempted to clean the Babula tank out, the most serious nuisances were caused, nuisances accompanied by a great prevalence of fevers in the J. J. Hospital. Before any tank is filled in, I think it should be insisted on as an essential condition that a certificate should be obtained from the executive engineer that the subsoil drainage of the locality in which the tank may be will remove quickly all the subsoil water flowing into the tank. Until drainage works are sufficiently advanced to remove the water which collects in the tanks of a locality, tanks ought not to be filled in. We have had an illustration of this in Khandia Tank Street. A large tank was filled in, and the result has been that the subsoil water of the street at high states of the tide rises up through the metal of the road.

In former reports I have referred to the waste of water, and the apprehensions I entertained of the effects of waste as seen in damp ground inside and outside buildings were not shared by some others, but I imagine that no one has now any doubts as to the reality of that waste and the evil effects which come of it. The measures taken to prevent waste, and the attention given to water pipes during the last year, have undoubtedly been beneficial and have had the effect of reducing the ill consequences of water running to waste. In one case in which waste of water had been carefully gauged by the Water Department, the Water Engineer wrote in reference to it: "I caused a meter to be fixed, with the result that the consumption "is found to be over 3,000 gallons per day. This works out to a payment of less "than ½ anna per 1,000 gallons. Taking the out-force of water at 3 annas per 1,000, "the payment should be over Rs. 2,000 per year, instead of about Rs. 350 as now "paid. The consumption per head is over 20 gallons against a desirable and efficient "allowance of six for such purposes as it is here used for." This, be it remembered, is waste of water at a group of buildings very imperfectly drained, and in consequence very damp.

It has occurred to me that at all chawls the water-pipes should be so placed that the water running to waste would flush the drains.

A very interesting correspondence has taken place on a letter from me suggesting that the scrub and long grass on the gathering grounds of the lakes Tansa, Vehar, and Tulsi should be cut down and burnt before the annual season of rainfall in the monsoon. During an inspection of the Tansa Lake in the last hot weather, I observed a quantity of long grass and scrub, more or less dead, just above the lake, and it seemed to me that the grass must soon rot and be washed down into the lake. The Forest Officer to whom the question was referred for opinion disapproved of the burning of the grass and scrub because of the denudation that, in his opinion, it would lead to. He wrote:—"The tree growth must also in due course disappear, and "the soil, having no protection, will be washed down the slopes into the lake and silt "it up; while, in the meantime, the leaves of the trees (which are now retained in "the grass and gradually incorporated in the soil, forming the mould so necessary "for plant life) will be blown or washed into the lake, and till all the trees were dead "the water of the lake would probably be worse than it can possibly be at present."

The question at first sight appears to be—"Will burning of the grass cause "denudation of the soil?"—that, however, is not the real question. The real point is this:—"Will burning of the grass as proposed by me cause denudation of the soil?" The Forest Officer has had, I think, in mind the burning of the soil and the turning up of it afterwards for agriculture. That is a totally different operation, I maintain. Last year, at Lanowli, I watched carefully the effect of burning the grass of a hill-slope, and I observed that the burning had not, after the rain came, the effect of denuding the soil. On the first moisture the tender shoots of grass came up and bound the earth firmly. The serious question is this: Is the preservation or conservation of all the grass and all the rubbish in the forests around the lakes compatible with the conservancy of the lakes and a pure supply of water. Clearly our policy ought to be to prevent all the impurities we can prevent descending into the lakes rather than to let the impurities in and have afterwards to adopt measures to intercept or destroy them. The preservation of forest means the preservation of mould, and with forest mould, some of which must be washed into the lakes, come forest fevers.

Towards the end of the year I had a correspondence with the G. I. P. Railway in regard to the importation of cases of cholera from Pandharpoor. Four cases within

two days were taken out of the train ill, two at Dadar, and the other two from other stations on the line. I wrote to the railway company inquiring whether any special precautions were taken for the examination of passengers coming from Pandharpoor. I was informed in reply "that at Dhond and Mammar the company's apothecary was "present on the platform for all trains conveying pilgrims.

"Special precautions were also taken at Barsi Road, and I am informed that only one female passenger showing symptoms of cholera was detected and prevented from travelling.

"In the village the district police were on the alert to prevent sick people from entering the railway premises.

"The cholera house was open and in charge of a Hospital Assistant, and it is stated that 19 cases were traced between the 30th October and 5th instant, and 11 deaths occurred.

"It is possible with such a rush of passengers for cases in the early stages to escape."

The subtleties that the Municipal Law encourages cannot be better illustrated than by the following case:—We have the power, under section 257, to call on a person to pave a sweepers' passage, and if the passage is not paved and the law complied with, there are certain penalties imposed for neglecting to comply with the law, but the passage must be a sweepers' passage and no other kind of passage. Let us take another passage between houses on which slops are thrown and which is in a constant state of soddenness, and, therefore, a danger to the buildings whose foundations are polluted through the water thrown on this passage. In this case we can do nothing because the passage is not a sweepers' passage. This is almost absurd, and it is certainly trifling with the public health and the public comfort.

It is deplorable that houses in the most crowded portions of the city can be rebuilt without leaving on one side an open space for ventilation and drainage. It seems of little avail having Building Byelaws when people can build houses where houses are closest together without leaving on one side a gully for open air, for light, and for drainage. Public attention is affected by the loss of life, however small, when a building falls, but here we have, through imperfection in the Municipal Law, many people annually poisoned by foul air. We have had cases of rapid poisoning through the foul air of sewers, men suddenly suffocated by mephitic vapours, and the cases have been the subject of prolonged legal inquiry, but here, in the case of buildings without a gully on one side, we have, although slower, not less certain, poisoning protected or tolerated by the law.

I have before referred to the dangerous positions in which water-closets have been constructed inside buildings. I have lately seen some plans on which it was proposed to construct water-closets near not only wells but alongside cook-rooms, and further this dangerous proposal could not be prevented. In many old buildings in the most crowded parts of the city the privies are near cook-rooms, and the result is cases of diarrhœa developing into cases of choleraic diarrhœa with the symptoms of cholera. It is a most dangerous position for cook-rooms to be placed in.

I am glad to be able to refer to the resolution of the corporation sanctioning the construction of an open drain where the foul ditch described in former reports flows and the sewage lies in pools on the ground between buildings:—"The drainage from "Parel to the north of Government House, Parel, on the south flows down in ditches "past the church in a wide cesspool to a ditch between buildings—between two rows "of dwellings—and between these buildings occupied by many people the sewage "soaks into the ground. On the north the drainage flows on to the low ground near "the railway station—ground flooded with sewage and wet from the leakage of a "water main."

Such is the ditch! The open drain sanctioned will take the place of the ditch. Money could not be better spent. It is a mistake to suppose that the money will be wasted when a system of drainage has been carried out in this locality. The ditch follows the course of a natural rain-water channel and it carries rain-water, and the same purpose this open drain will serve. The open drain will do harmlessly what the ditch could not do—carry sewage away from dwellings. It will give great relief to the people of the locality, and it was the only means by which speedy relief could have been given.

About a mile and-a-half of open drains will be constructed with open drain connections from the buildings. The sides of the drains will be pitched and embankments formed which may be used for bathing, so that the people, instead of standing in pools of water in front of their dwellings, will be able to stand and walk on dry ground, and where they bathe the ground will not be flooded nor made into a

pool of water and mud. It is true that the sewage will only be carried away from buildings to low-lying ground far from buildings, but to the people living in this locality what comfort these open drains will bring?

I am glad to state that tanks have been sanctioned to collect the waste water where water from stand-pipes was running to waste and washing away footpaths in Parel, to relieve pressure in the water-mains, and the water can now be used for bathing or other purposes.

In one case in which I objected to the position of a water-closet within two feet of a well, the Executive Engineer was of opinion that there is nothing in the Municipal Act under which the Commissioner can fix a particular site or object to a site proposed by a party for a water-closet or a privy. But in Byelaw No. 34, however, such power is given to him for privies only, and the Executive Engineer is, therefore, of opinion that the municipality cannot prevent a man from building his water-closet wherever he chooses to do so. As the question was one of great importance, the opinion of the Municipal Solicitors was asked. The solicitors were of opinion that "the Municipal "Act gives no power to the Commissioner to prescribe the position in which an owner "of property is to place a water-closet which he proposes to build, nor does it contain "any provision which enables the Commissioner to prevent such an owner from "building his water-closet wherever he chooses to do so, provided of course that the "position chosen is not inconsistent with the due observance and fulfiment of the "provisions of section 251. Byelaw No. 34 of the building byelaws does not extend "to, and cannot possibly be held to apply to, water-closets."

Very great anxiety has been caused to me by the number of applications we have received to construct water-closets. A person who has not space for a privy thinks that he is wise in putting a water-closet where he would not be permitted to build a privy. I referred to this in my last annual report, and I have also referred to it in other reports. If the rules proposed by the Committee, consisting of the Executive Engineer, the Special Drainage Engineer, the Drainage Engineer, and the Health Officer, appointed by the Commissioner to consider the system of house-connections for Colaba be adopted and carried out in the city generally, the danger from water-closets will be reduced to a minimum. A curious experience occurred while this Committee was sitting. On one day when I happened to be strongly objecting to the construction of water-closets in bathrooms, information came to us that on that morning in one of the finest buildings in the Fort the sewage had regurgitated back from the street sewer up through the water-closets. We went in consequence and inspected the building and found an abominable nuisance, an odour which may be described as of putrid paints. This led to the inspection of another building not far away, in which there are water-closets, and in this building we observed outside the water-closets of all places a tiffin room for "young ladies."

I am sorry that practically no progress has been made in the works necessary to the making of connexions between sewers, some of which have been constructed as far back as 1880, a list of which I gave in the last annual report, and buildings. The question as to whom the connexions were to be made by, was, however, coming to a final stage of discussion. The question of most urgency, after the construction of drains to carry away sewage and water, is the question of connexions between buildings and sewers. There are sewers on the east end of the Island that have been ready for use for some 16 years to which connexions have not yet been completed. Fortunately, on that side of the Island in the most crowded portions there are old channels, more or less worn away by cleaning and scraping, originally intended for rain-water, by which sewage and rain-water can flow away. But on other sides and in other parts of the Island, there are only ditches, the sides of which have at one time been roughly formed by the Health Department collecting and arranging some stones to form banks between which the sewage might flow, from which most serious nuisances come. Unless that connexions are promptly made, I fear that the position of some of the sewers will be forgotten and that they will, as occurred in Kamathipura many years ago, silt up. There is no question the most careful supervision is necessary, no matter by whom house-connexions are made, and a very large establishment ought to be, and will have to be, employed for supervision. The construction of house connexions in crowded portions of the city is attended by many difficulties. In fact, if house-connexion work is to be thoroughly supervised, it involves an expenditure for supervision which the municipality have little idea of. In the narrow lanes and in gullies in which a man can scarcely turn it is most difficult to supervise the work.

It seems to me that the only immediate remedy for the serious nuisances that now exist in Parel and the suburbs is the construction of a number of intercepting open drains to carry sewage and water away from dwellings.

I am glad that a system of drainage which will embrace the Nagpadas, districts specially referred to in my last annual report, has been sanctioned.

As yet connexions have not been made to the Shone system in Colaba.

I would give an instance in a district now forming a portion of the city of the difficulties which the absence of drains causes. The district is Byculla, and the locality is the important one of Gilder Street, the north portion of which has not a sewer. There are most serious nuisances in the locality around groups of chawls off this street caused by pools of water and sewage. The Health Department prosecuted in order to abate the nuisances and obtained the construction of cesspools. The cesspools, which are masonry tanks, merely embank the sewage during the fair weather. In the wet weather the tanks overflow and sewage and water cover the open ground to the foundations of the buildings. The Drainage Engineer and I made a long inspection of the locality, the time of the year being the rainy season. The ground around the chawls was covered with water. It occurred to the Drainage Engineer that a connexion might be made with the rain-water drain in Gilder Street, but on taking the levels it was found that the storm-water drain was higher than the level of the dwellings, so that a connexion could not be made. This is a very important locality, in which there are, as I have now described them, serious nuisances. Further south of the Bellasis Bridge the same difficulties have occurred owing to, not the absence of drainage, but the low level of the ground. There is a group of buildings in that locality consisting of six chawls, and although they have plinths above the level of the surrounding ground, they are still too low to be connected with the system of drainage in the district. The result is that all the water and sewage has to be used for irrigation around the dwellings.

A great deal of attention has been given during the year to the arrangements for the filtration of the water supply. I strongly advocated the improvement of the ventilation of the chambers in which the filter beds are placed, and improvements have been effected. Still in the hot season the temperature in the filtration chambers is some 5 degrees above the temperature in the shade in the outer air. The water in the reservoirs ought to be kept as cool as possible.

The general death-rate is very unequally distributed; the Water Division having a mortality of 3·02, the Fort, South, 8·60, the Esplanade 12·51, and Chaopati a death-rate of 14·76. At the other extreme we find Second Nagpada with a mortality of 50·61, Kamathipura with a mortality of 44·85, Tardeo with a mortality of 40·51, and Khara Talao with a mortality of 39·24.

The highest mortality has occurred in Second Nagpada. I am glad to be able to record that a system of drainage has been sanctioned for the Nagpadas, and that after many years there is a hope of this district being drained. A system of subsoil drainage will, however, have eventually to be carried out in the Nagpadas. The locality of Kandia Street to which I have referred as exhibiting a remarkable fluctuation and rise in the subsoil drainage up to the road level is in Second Nagpada.

The second highest mortality has occured in Kamathipura. The measures necessary for the improvement of Kamathipura, I have described fully in the following words in the last annual report:—"I have for many years described the insanitary conditions " influencing the health of the people of this locality, and enhancing the mortality of " Kamathipura, and I need not now do more than briefly refer to some of these " conditions. The conditions to which I am now drawing attention are the high level " of the subsoil water and the nature of the soil. In the annual report for 1892–93 I " referred to the mortality in the locality of Kamathipura as follows:—'Although " 'the mortality in Kamathipura is high, it is not the highest as in the last year. There " 'are two improvements which should be carried out in Kamathipura—the drainage of " 'the subsoil water which is almost up to the surface even in the hot season, and the " 'improvement of buildings. A member of the Corporation, who has come to live " 'in the old Kamathipura district, has seen to his amazement the water rising up " 'through the floor of his house. I told him it would be so, and even worse, before the " 'rains were over. Kamathipura is now one of the densely populated localities.'".

Tardeo, the locality of third highest mortality, is very damp, and localities in it are very low lying and made up also of artificial soil. Portions of this district were, many years ago, reclaimed with refuse, traces of which are still found. There is, moreover, a very numerous and poor population in the locality, and, in addition, an increasing number of factory hands.

Umarkhari occupies the fifth place. I am glad that a system of drainage, which will embrace this district, has been sanctioned.

Chukla occupies the sixth place. It is a district of intense crowding, having had as many as 624 persons to an acre in 1891. The houses are also very imperfectly ventilated, being dark and overcrowded. The district has a number of sewers to which connexions have not yet been made. Not only should connexions be made to these sewers and the system of drainage completed, but an open space for which there is great need should be provided in the district.

The mortality under one year of age and under very closely indicates the insanitary conditions and the chances of life in districts. For instance, the five sections in which the highest mortality amongst children under one year of age has occurred, are Tardeo, Second Nagpada, First Nagpada, and Umarkhari. These are all undoubtedly sections of very insanitary conditions, both within and without buildings.

The mortality by class is an indication of the conditions influencing each community and, in consequence, the mortality by class is always of very great interest. Of the four principal classes the mortality, compared with the year before, is very much lower among Mussulman, the reduction of mortality in this community being equal to 2·80 per 1,000, and a little higher amongst Europeans. The mortality of European males is a little lower than in 1894, being 18·72 against 18·97, representing a difference of two deaths. The mortality of European females is 2·21 higher, the excess, I believe, being due to European females when seriously ill coming here either for medical treatment or on their way to some other place for a change.

The mortality amongst Parsees is 1·14 higher than in 1894, but ·84 lower than in 1892. Although the total mortality of Parsees is 1·14 higher than in 1894, the mortality of males is actually lower and the total enhancement is caused by a higher female death-rate. The increase in female mortality, I am inclined to believe, is due to a number of females, when seriously ill, coming to Bombay for medical assistance. But compared with the death-rate in the great mass of the population, the mortality amongst Parsee females is very low.

Excluding the small communities liable to great fluctuation in population, the highest mortality (54·14) has occurred amongst Hindu Low-Caste, although the death-rate is less than in the year before. It has ever been so. The mortality will always remain high amongst Hindu Low-Caste. Whenever the seasons have been unfavourable and disease rife, Hindu Low-Caste have suffered most. They are very poor, living in crowded localities, and in the most insanitary buildings of these localities, several families in one room, a custom unknown in other classes, on damp floors and eating the poorest food. I can only suggest what I suggested in 1885, that the Municipality should build dwellings for them and give medical relief and charity.

In all the chief classes the female mortality is much in excess of the male. There are many influences unfavourably affecting the chances of female life during the child-bearing age: of these, imperfect house ventilation and seclusion of life in ill-ventilated and ill-drained and overcrowded buildings amidst privation or poverty are the most evident, and those to which attention is first directed.

The mortality from the chief death causes is shown in the table following :—

Table showing the Number of Deaths and the Death-rate from Different Causes in 1895.

Causes of Death.	Number of Deaths.	Death-rate per 1,000 of Population.
Small-pox	270	·33
Measles	544	·66
Fevers	6,404	7·79
Cholera	90	·11
Phthisis	3,610	4·39
Diseases of the Nervous System	2,044	2·49
„ „ Respiratory System	4,565	5·56
Diarrhœa	1,188	1·45
Dysentery	625	·76
Accidents	488	·59
All other causes, except Still-born	5,253	6·39
TOTAL	25,081	30·52

The mortality from small-pox, measles, cholera, and fevers in 1894 and 1895 is contrasted in the table following :—

Causes.	1894.	1895.
Small-pox	·6	·33
Measles	·96	·66
Cholera	·52	·11
Fevers	7·86	7·79

It will be observed that there has been a decrease in the mortality from the chief death causes, namely, fevers, small-pox, measles, and cholera equal to 2·73 per 1,000.

The mortality by age periods follows nearly the same incidence as in former years. The mortality of male children of two years of age and under is higher than of females; while from two years of age and upwards the mortality amongst female children commences to rise until in the nubile period it is more than double the male mortality. The causes of this terrible fatality amongst women and young women I have frequently referred to. The high female mortality at this important period of life is one of the most serious influences enhancing the mortality. The terrible loss of female life indicated in these tables may be diminished through medical relief and more prosperous and economic conditions and by better house sanitation. Between 9 and 40 years of age the female mortality is more than double the male. This is a very deplorable loss of life, and it falls heaviest on the following classes, viz.: Jains, Brahmins, Musalman, and Native Christians. The incidence of the female mortality is a great factor in the fluctuation of the death-rate of localities. The localities of highest mortality are the localities with the highest female death-rate. High district mortality indicates a sacrifice of adult female life and a high death-rate of children.

Measles.—The mortality from measles is much less than in the last year; 544 deaths were registered, being 243 less than in 1894, and 28 more than the average. With the lower mortality from small-pox there has also been a decrease in the number of deaths from measles. Of the large communities, the highest mortality has occurred amongst Hindu Low-Caste, then follow Jews, and Eurasians.

Small-pox.—From small-pox 270 deaths were registered, being 261 less than in the last year and 36 less than the average. There is, as I have stated before, a remarkable relation between the incidence of the mortality from both small-pox and measles. Of the large communities, the highest mortality occurred amongst Native Christians and the mass of the Hindu population.

Fevers.—The mortality from fevers is 54 less than in the last year and 272 less than the average. 5,150 of the deaths from fevers were referred to remittent fever, being 140 less than in the last year, and 289 less than the average. Thirty-five were referred to enteric fever, being nine more than in the last year and 15 more than the average. The increase in the mortality from enteric fever must, I think, be ascribed to more cases having been treated by medical men and therefore more accurate registration. The mortality from fevers acquired its highest incidence in the month of May. In the same month in the previous two years the highest mortality from fevers also occurred.

Table showing the Mortality from Fevers according to Months.

Months.	Number of Deaths.	Mortality per 1,000 of Population.
January	555	8·10
February	507	7·40
March	585	8·54
April	570	8·32
May	764	11·15
June	591	8·63
July	477	6·96
August	522	7·62
September	422	6·11
October	387	5·65
November	469	6·84
December	555	8·10
TOTAL	6,404	7·79

The incidence of the mortality by months indicates in this year as in the previous year that the mortality from fevers is highest at the two periods of greatest subsoil fluctuation. I would draw attention to the importance of this phenomenon.

The incidence of the mortality by sections is very interesting. The section of highest mortality in 1894, namely Sewri (11·54), is again the section of highest mortality in 1895. The section of second highest mortality is Khara Talao (10·35), and the section of third highest mortality Mandvi (10·24). The first section, Sewri, is a district without drains but with an increasing population of mill-hands, and the high mortality is therefore, to some degree, probably connected with immigration and the increase of population. Khara Talao is a section with drains, mere rain-water channels, very imperfectly ventilated, very dilapidated, and with very little fall. I have so often described the imperfect sanitary state of Mandvi that I need not now do more than refer to the description of the district in the last Annual Report. There is a large sewer, giving most insanitary communications, running through the east of Mandvi, a sewer which from its high level, is difficult to flush except at high tide and very imperfectly ventilated. The sewer I refer to is the Frere Road sewer.

Cholera.—A very small mortality from cholera, namely, 90 deaths, was registered. The mortality is 336 less than in the last year and 112 less than the average. The disease cannot be considered to have been epidemic during the year. The mortality has been very low, in fact, most of the cases might have registered as choleraic diarrhœa. In the following sections, viz., Parel (0·45) and Mahim (0·37), the highest mortality occurred; they are in the suburbs, one forming the north boundary of the island.

Phthisis.—The mortality from phthisis is a little higher than in the last year. 3,610 deaths were registered, being 22 more than in the last year and 348 higher than the average. The death-rate is equal to 4 39 per 1,000 of population.

The mortality by sections is interesting. The five districts of highest mortality in 1894–95 are shown in a table following. It will be observed that the highest death-rate occurred in 2nd Nagpada, and that Umarkhari, which was the district of second highest mortality in 1894, is not amongst the five districts of highest mortality in this year. A system of drainage has been sanctioned for the Nagpadas. In regard to the reduction of mortality in Umarkhari, I would refer to the remarks in the last Annual Report.

The HIGHEST INCIDENCE of MORTALITY from the CHIEF DEATH CAUSES shown by SECTIONS.

All Causes.		Fevers.		Diseases of the Respiratory System.		Phthisis.		Debility.	
2nd Nagpada	50·61	Sewri	11·54	2nd Nagpada	10·28	2nd Nagpada	9·96	2nd Nagpada	7·14

Fort, North	3·22	Umarkhari	1·77	Mazagon	·35	Byculla	·84	Kamathipura	·13
Kamathipura	2·97	Sewri	1·64	Kumbharwada	·34	Mandvi	·77	Sion	·10

Diseases of the Respiratory System.—There has been a very large reduction in the mortality from the diseases of the respiratory system. 4,565 deaths were registered,

being 820 less than in the last year and 115 more than the average. Of the deaths from diseases of the respiratory system, 2,632 were referred to bronchitis, being 721 less than in the last year and 137 less than the average; 1,354 were ascribed to pneumonia, being 47 more than the last year and 298 more than the average.

Digestive System.—The mortality from diseases of the digestive system is 594 less than the last year and 120 more than the average of the last five years. Of the deaths from diseases of the digestive system, 1,188 were ascribed to diarrhœa, being 410 less than in the last year and 13 more than the average; and 625 were referred to dysentery, being 121 less than in the last year and 45 more than the average. To all other diseases of the digestive system 678 deaths were ascribed, being 63 less than in the last year and 62 more than the average.

From diseases of the nervous system 2,044 deaths were registered, being 355 less than in the last year and 195 less than the average.

There has been a considerable increase in the number of births reported this year. 15,684 living and 1,470 still-born births were registered. Of the living births 8,150 were males and 7,534 females. The proportion of females to males by the census of 1891 was as 170·60 to 100, and, assuming that there were 100 males to 100 females, the birth-rate would be equal to 32·55 per 1,000 of population. This is the largest number of births registered since 1889.

APPENDIX.

No. 1.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER with the GOVERNMENT OF INDIA for 1895.

The year will be memorable for the failure over a great part of India of the usual autumn rains. From the cessation of the rains in September until the end of the year there was "practically or absolutely" no rain over a large part of the country. The rainfall of the whole year for the whole area of India was 3·38 in defect. Had this deficiency been uniformly distributed no calamitous failure of crops need have followed; but whilst, in the last three months of the year, the rainfall was in moderate excess in the southern part of the peninsula and in East Bengal and Cachar, there "was practically *nil* over the whole of Northern and Central India." The result has been a failure of crops and consequent scarcity of food for man and beast more wide-spread and severe than any hitherto recorded. Although this failure and the consequent scarcity began at once to make themselves felt, it will not be until the next year that their effects on the health of the country will become fully manifest. But the speed with which failure of the crops was followed by scarcity intensifying into famine shows the hand-to-mouth mode of life forced upon a people of great fecundity, multiplying without check within an area which their conservative habits forbid them to transgress in numbers sufficient to exercise any appreciable relief for the pressure of over-population.

2. *European Army of India.*—The instructions and suggestions of the Army Sanitary Commission in their review of the Report for 1893 have led to a thorough revision of the tables, with the welcome result that these now appear in a new and simpler form, whilst their number has been reduced by exactly half. Yet, as the Sanitary Commissioner remarks, "not only has nothing of "importance been omitted, but a considerable amount of fresh information has been furnished."

3. Although, judging from the admission and death rates, the health of the European Army was better than during the preceding year, yet the constantly sick rate per 1,000 of strength was higher. Whilst out of every 1,000 men only 60 were on the average constantly sick in the 10 years 1870–79, and only 73 in the 10 years 1881–90, the ratio rose to 92 in 1894, and now in the year under report to 94. It is disappointing to find that in spite of the advance of knowledge of disease and the sustained sanitary endeavour to maintain the health and consequent efficiency of the Army, only 906 are fit for duty out of every 1,000 men, as compared with 943 for the period included between 1870 and 1879. This result is not altogether to be explained by the change in the constitution of the Army; for the influence of the short-service system had come into effect before 1880, and yet the average number constantly sick in the years 1881–90 was only 73 as compared with 94 in the year under report. "The progressive increase in the constantly sick rate is probably "connected with the progressive increase in the number of cases of enteric fever and of venereal "disease, and with the increase since 1890 of influenzal respiratory diseases; that is, with the "increase of diseases which keep men long in hospital."

4. The ratio of admissions into hospital, amounting to 1,462 per 1,000 of strength, was somewhat less than that for 1894, and also than the average for the 10-year periods 1870–79 and 1881–90. The chief causes of admission were venereal diseases and ague. The former caused no less than 36 per cent. and the latter 23 per cent. of the total sickness. But, as usual, the chief factors in the production of sickness were not the chief causes of mortality. Of every 100 men of our European Army of young soldiers who died during the year, 44 died of enteric fever. The total number of deaths from this disease was 477; whilst, according to Table LIII., there were only 10 deaths from ague and 15 from venereal diseases. But, although the chief causes of sickness were not also the chief causes of mortality, they took the foremost place amongst the causes for invaliding.

5. Taking the year 1877 as the period when the short-service system began to seriously affect India, it may be said that, accompanying the increase of the proportion in the army of young and unmarried soldiers, there has been increased admission from enteric fever, ague, alcoholism, and venereal diseases. But whilst increase of sickness from these diseases has been associated with the change in the constitution of the army consequent on the introduction of the short-service system, there has been on the other hand diminished admission, death and invaliding ratios under all the remaining and more numerous headings. During the year, only 44 admissions and 32 deaths are recorded from cholera, against 209 admissions and 149 deaths in the previous year; whilst the ratio of mortality per 1,000 of strength from this disease has fallen from an average ratio of 3·22 in the 10 years 1870–79, to 0·45. This decrease may fairly be credited to improved hygiene. The decrease in remittent and simple and continued fever is probably due to change in diagnosis and

transfer to the head of enteric fever. Admissions from liver disease, the disease of the old soldier, have diminished by more than half since the introduction of the short-service system. In short, the alteration in the constitution of the army has been followed by increase in sickness and mortality from some diseases and by a compensating decrease from others, the outcome being that the total mortality from all causes has been reduced.

6. In the distribution of the European Army in India strategic considerations must of course be paramount; but the information given regarding the sickness and mortality prevailing in the geographical groups shown in the map facing page 18 might be useful as a guide in suggesting the location of troops when choice of locality is practicable. An examination of the health statistics of the several geographical groups shows, for example, that, whilst out of every 1,000 of the 7,068 men who on the average during the year formed the garrison of the Gangetic plain and Chutia Nagpur, 105 were constantly sick, or in other words, whilst of each 1,000 men only 894 were fit for duty, on the other hand, of the 3,781 forming the average strength of the garrison of Southern India, only 71 of each 1,000 were constantly sick, that is to say, 928 of each 1,000 of strength were fit for duty. Fractions have been omitted from the foregoing numbers. The 1,562 men who formed the garrison of the Western Coast group enjoyed nearly the same immunity from sickness as those of the Southern India group. In both groups the ratios of deaths from enteric fever were respectively 1·32 and 2·56 per 1,000 of strength, as compared with 7·36 in the Gangetic plain and Chutia Nagpur. Moreover, whilst in neither of these groups was there a single death from cholera, the ratio of deaths from this disease in the Gangetic plain and Chutia Nagpur was 2·12 of every 1,000 men. A glance at the table on page 20 will show that this comparative immunity from enteric fever and cholera was not confined to the year under report, but characterized the preceding year and the decade 1882–91. The report supplies abundant and exact information for further suggestive comparisons between the different geographical groups. Even hill stations compare unfavourably from a health point of view with Southern India and the Western Coast. In these hill stations the ratio of men constantly sick is higher, and the mortality from enteric fever greatly higher.

7. *Principal Diseases.*—Amongst the European troops *cholera* was fortunately in comparative abeyance, only 32 deaths having been caused by it against 149 in the previous year. The disease prevailed in epidemic form only in Fyzabad and Secunderabad. Beyond evacuating quarters no general movement of a body of European troops was made except at Fyzabad, and no case of cholera occurred after such movement. Likewise, in the 10 cases in which bodies of Native troops were moved, the moves were successful in all cases except one. In addition, prisoners were moved out of jail on 11 occasions, and no fresh case occurred after any of the moves. Prompt evacuation of the affected locality has been proved by the experience of a long succession of years to be the most successful method of dealing with outbreaks of cholera; and the experience of the year under report adds fresh testimony to the wisdom of this course. Another year of research into the vexed question of the exact cause of cholera leaves the question pretty much where it was before. Those who persistently assert that the *comma bacillus* is the one agent in the production of the disease will not find their assertion supported by the systematic examination of choleraic material continued at Calcutta. These investigations confirm the conclusion that, so far as Calcutta and its neighbourhood are concerned, "cholera is either an exceptionally rare disease, or one which is not necessarily "characterized by the presence and prevalence of any one species of vibrionic organisms within the "digestive tract, and has yielded additional evidence that there is no scientific ground whatever "for the assumption that all the vibrionic forms are mere varieties of one and the same species, and "that any such assumption can only be regarded as an arbitrary attempt to force facts to agree "with popular beliefs." But whilst these examinations are being carried out by experts, the practical means of preventing cholera, and of dealing with it when prevention has failed, are no longer a question of dispute. Persistent efforts to prevent disease generally, by an elaborate system of scientific sanitation, have already reduced cholera in the European Army to a fraction of its former fatality. This is exemplified by the figures for the year under report, when only 32 deaths were caused by this disease in an army of an average strength of 71,031 men. When, in spite of our sanitary efforts to prevent it, cholera does break out, prompt movement of the troops from the affected locality has rarely failed to arrest the further progress of the disease, provided the movement has been properly effected. This also is exemplified by the experience of 1895.

8. But whilst cholera prevalence is thus being steadily reduced, *enteric fever*, which has only come to be clearly identified as a distinct disease within recent times, has attained the foremost place as a cause of mortality in our short-service Army of India. During the year under report, 1,870 admissions, and 447 deaths were attributed to enteric fever; whilst 220 men were constantly sick from it, and each case lasted on the average 52 days. Notwithstanding that more is known about this disease than formerly, increased knowledge of it has not yet led to any decrease in its prevalence. On the contrary, "as compared with the corresponding ratios of 1894, the admission and "death ratios rose respectively by 5·4 and 0·97 per 1,000 of strength." So late as 1877 the recorded death-rate was only 1·60 from enteric fever in India; in 1895 it was 6·72. Undoubtedly part of this increase is due to the increased frequency with which of late years the diagnosis of enteric fever has been made, as well as to increased susceptibility to the disease on the part of the army from youth and recent arrival. Nearly 17 pages of the Report are devoted to a useful *résumé* of what is at present known and believed regarding enteric fever. The bewildering conflict of opposing views held by those who claim to be considered experts in the bacteriological investigation of the disease leaves us in doubt as to which of these views should be accepted. But of the wisdom

of the Sanitary Commissioner's conclusions there can be no room for doubt. "Finally," he says, "it must be borne in mind that, though nowadays more is known about enteric fever than in former "times, still much remains involved in mystery; and that as all the avenues of approach of the "disease may not have been discovered, no single point of hygiene should be neglected."

9. *Venereal diseases* have still further increased in prevalence during the year under report, the admission rate caused by them having reached 522·3 per 1,000 of strength, the highest hitherto recorded. The Army Sanitary Commission having so recently expressed their views on the question of the prevalence of these diseases amongst our British troops in India, it is not considered necessary to refer at length to the subject in this place. We may remark, however, that the great and increasing prevalence of this class of disease in India is most lamentable, and we are glad to learn that an earnest attempt is being made on the part of the Indian Government to devise some measures for dealing with it. The evil has reached dimensions which threaten to be ruinous to the efficiency of the European Army in India, to say nothing of its far-reaching and dreadful effects on a number of innocent persons in this country.

10. *Native Army.*—Although the ratio of mortality was nearly the same in both the European and Native Armies, having been 15·26 in the former and 15·71 in the latter, including those absent at the time of their death, the ratio of admissions into hospital among Native troops was only 794 per 1,000 of strength against 1,462 amongst European troops; whilst the constantly sick ratio was only 30 amongst the former as compared with 94 amongst the latter. The contrast between the two armies in respect of the causes to which sickness and mortality were due is striking. Whilst in the European Army 44 out of every 100 deaths were caused by *enteric fever*, only a fraction of 0·6 is recorded against this disease in the Native Army. On the other hand, 42 out of every 100 deaths resulted from *respiratory diseases* in the Native Army, and only 3·7 in the European Army. The cause of the comparative immunity of the Native Army from enteric fever is still more or less uncertain; but with regard to the greater fatality from respiratory diseases, the Sanitary Commissioner writes of *pneumonia*, the most fatal of these:—"The Europeans suffered much less than the "Natives, probably because they are more accustomed to cold, because they are better clothed, and "because they are more nutritiously fed." These reasons suggest some of the measures which might be adopted with the view of lessening the liability of our Native soldiers to the disease.

11. Whilst the incidence of enteric fever and respiratory diseases is so strikingly different in the two armies, the mortality from some of the other principal diseases was much the same in both. Of every 100 deaths in the European Army, 3·0 were due to *cholera*, as compared with 3·5 in the Native Army; and whilst of every 100 deaths in the former 7·3 were caused by *bowel complaints*, 6·6 were due to the same diseases in the latter.

12. The comparative liability of the two armies to sickness and mortality from *ague* may also be noted. Whilst of the admissions into hospital of European troops 23 per cent. were due to ague, the percentage amongst Native troops was 36; and whilst of every 100 deaths amongst the former 1·7 were due to ague, the percentage was 5·1 amongst the latter. Perhaps the explanation of this contrast may, to some extent, be the same as that already given of the greater liability of Native troops to pneumonia.

13. From *venereal diseases* the Native Army enjoyed its usual immunity. The ratio of admissions into hospital per 1,000 of strength was only 31·3, as compared with 522·3 in the European Army.

14. In our Memorandum for 1894, we suggested that one of the causes of the prevalence of respiratory diseases in the Native Army might perhaps be found in the overcrowding and defective ventilation reported to exist in the quarters occupied by some of the corps. In Table XXX. of the Report for 1895 giving a brief statement of sanitary defects existing in the lines of the most unhealthy regiments, we find that in the case of 11 out of those 48 regiments overcrowding or defects in ventilation are reported. The influence of these insanitary conditions in the production of disease generally, and more especially of respiratory diseases, is well known.

15. *Jails.*—"The year was one of much sickness, though the death-rate was considerably reduced." As usual, *ague* was one of the chief causes of sickness. Of the total admissions into hospital, 35 per cent. were due to this disease, the percentage being nearly the same as in the Native Army, in which it was 36. As from year to year they have hitherto been, *bowel complaints* and *respiratory diseases* were the chief causes of mortality. During the year under report, *dysentery* caused 26 per cent., and *pneumonia* 14 per cent. of the total number of deaths. In the European and Native Armies, as in jails, the increase in respiratory diseases is said to have been at least to a large extent due to the epidemic of influenza which began in 1890. Of the total 2,936 deaths, which according to Table LIII., took place in Indian jails during 1895, no fewer than 1,003 were due to dysentery and diarrhœa. Prevalence of bowel complaints points to the need for improvement, more especially in the quantity, quality, or cooking of the prisoners' rations. The more fatal of the respiratory diseases, pneumonia and tubercle of the lungs, caused together 608 deaths. From an examination of Table XLIV., we find recorded against 39 of the 68 most unhealthy jails that they were overcrowded to varying degrees, or that their ventilation was in some respect defective. Taking into consideration the heavy mortality from respiratory diseases, a serious responsibility rests on those who permit the continuance of conditions universally recognised to be powerful factors in the causation of these diseases. Regarding the mortality from pneumonia in the Punjab jails, the Sanitary Commissioner observes:—"It seems desirable that extra clothing should be issued during the cold

" season to the prisoners in those jails where this disease is most prevalent, and that hospital " accommodation with proper appliances for keeping the air at an equitable temperature should be " provided for patients with respiratory diseases."

16. The subjects dealt with in the remaining sections of the Report have been, as far as seems needful, separately noticed by us in our memoranda on the several provincial sanitary and vaccination reports.

19th July 1897.

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner for Bengal for 1895.

1. Taking into account the decrease of the death-rate, it may be concluded that, for the Province as a whole, the year was healthier than its predecessor. It is pointed out by the Government of India, that no information has been given concerning the influence of meteorological conditions and the price of food-grains on the general health of the people, and the request made that this may not be omitted from future reports.

2. *Vital Statistics.*—The *birth-rate* shows a substantial increase over that recorded for 1894, whilst there was a marked decrease in the *death-rate*. Compared with the birth-rate of 50 per 1,000 of population estimated by actuaries, 34·59, the rate recorded for 1895, shows that registration, although it has greatly improved since 1892, is still defective. Similarly, the divergence between 31·39, the recorded death-rate, and 44, the rate estimated by actuaries, is too wide to be explained, except on the supposition that a large proportion of the deaths escaped registration. The question of improving the registering agency is stated, in the Government Resolution on the Report, to be under consideration in connection with a general scheme for re-organising the Sanitary Department in Bengal. But the satisfactory results obtained, from what appears to be the same system of registration in the North-Western Provinces and the Punjab, would suggest that the system is probably not so much in fault as the way in which it is carried out.

3. *History of Chief Diseases.*—Although the recorded number of deaths from *cholera* was less than during the preceding year, it reached 177,087, or a ratio of 2·49 per 1000, of population, as compared with 3·32 in 1894. Mortality from the disease varied from the high ratio of 7·08 deaths per 1,000 of its population of 2,395,602 inhabitants in the Dacca district, to 0·03 in Lohardaga. The Sanitary Commissioner thinks that "in the present undetermined state of the etiology of this mysterious disease," it would serve no useful purpose to attempt an explanation of the varying degrees of its virulence, or to enter into the difficult question of the cause of immunity of persons and places. Whilst, like most sanitarians, attaching the greatest importance to the provision of a pure water-supply as a means of preventing cholera, he would not confine attention so this alone. "The " importance of drainage and stricter conservancy has been repeatedly brought to notice, as well as " the necessity of improved means for the supply, and still more, for the distribution of water; " indeed, the great value of a pure water-supply, as a preventive of cholera, can hardly be over " estimated, nor the great importance of drawing it from a source beyond suspicion of contamination." He would like to see villages provided with sanitary wells—in other words, with wells having their water properly protected against pollution. In our memorandum on last year's sanitary report for Bengal, we described what Dr. Banks, the Civil Surgeon of Puri, had already accomplished in this direction. Along the pilgrim roads leading to Puri, closed pump wells are provided for the supply of drinking water, which is thus secured against pollution. If the inhabitants of rural Bengal could be educated to appreciate the value of, and carry into effect an arrangement which, without infringing their caste customs, preserves the purity of their drinking water at little cost, a sanitary improvement of a more far-reaching nature than the supply of filtered pipe-water to the towns of the province would be brought about. After all, the inhabitants of the town circles do not constitute more than about one-twentieth of the population of Bengal.

4. *Small-pox.*—The mortality from this disease exceeded that of the preceding year, and was also considerably greater than the average of the past ten years. It comes as a surprise to find the city of Calcutta the centre of a severe epidemic of this disease, which "at one time threatened to " create considerable havoc in the surrounding districts, but the latter, thanks to their high degree " of protection, are to be congratulated on the comparatively small number of cases that occurred in " them, and the low mortality." The Sanitary Commissioner takes care to explain that Calcutta is not under the jurisdiction of the Bengal Vaccination Department. The more would seem to be the pity, if we may judge from results. For the protection of its inhabitants against this preventible disease, the Municipal Corporation has its own arrangements, supervised by its own special Health Officer. Seeing that, whilst the mortality from small-pox averaged only 0·18 for the province of Bengal, as a whole, it was 3·25, or nearly 20 times greater in the town of Calcutta; these arrangements, or their supervision, would appear to need improvement. As usual, young children suffered more in proportion than adults. Of the 13,020 deaths from small-pox, no fewer than 6,631, or more than half, occurred amongst children under 12 years; and of this latter number 1,924, occurred amongst infants under one year of age. When we refer to the separate vaccination report

the explanation is apparent. In the table given in paragraph 6 of the report, it is shown that, whilst there were 2,460,469 "surviving population under one year available for vaccination," only 416,307 were protected against small-pox by vaccination, or nearly one in six. As Dr. Dyson remarks, the degree of protection afforded to infants under one year of age is the proper test of the working of the Vaccination Department. In connection with the epidemic of small-pox in Calcutta, we find, on referring to the table given on pages 16 and 17 of the separate vaccination report, that of the total number of operations, amounting to 18,913, only 154 were inspected by the Health Officer, and that, of this small number, only 69 were found to be successful.

In paragraph 15 of his report on vaccination, the Sanitary Commissioner gives an interesting statement with the object of showing the comparative value of the three methods of vaccination at present practised in Bengal, viz., direct from the calf, with lanoline paste, and the arm-to-arm method with human lymph. If the value of each is to be estimated by the resulting ratio of success, the last of the three, or arm-to-arm method, is the best; next to this comes vaccination with lymph taken direct from the calf; whilst, as might have been expected, the lanoline-paste method is the least successful of the three. Dr. Dyson is himself in favour of lymph used direct from calves. He says he is not prepared to admit that lymph "when properly procured by the arm-to-arm process, and "from healthy children, is of equal value to the lymph procured directly from calves"; but, even supposing it to be the case, the difficulty is always to procure healthy subjects. "Invariably," he adds, "the children used as vaccinifers are low caste and unhealthy." This statement is surely too absolute. Unhealthiness is not an invariable characteristic of low-caste children.

We are glad to see that, as the result of increased strictness of supervision, the percentage of successful cases of vaccination has fallen from 99·26 in the previous triennial period, to 95·38 in the triennial period 1893–96. Anyone having a practical acquaintance with vaccination work in India cannot help suspecting the accuracy of the returns which show a percentage of 99 and upwards of successful cases. The statement that "the degree of protection afforded by vaccination bears a definite "relation to the number of successful vaccination marks" needs some qualification. If the operation is performed by inserting the vaccine lymph by means of a puncture with a lancet, the resulting cicatrix will indicate a less protective value than if the lymph were inserted into the scratches made by the vaccination needle used in some provinces. In the latter case the cicatrix, or "foveated area," may be several times more extensive than the cicatrix, following a puncture with a lancet. When the needle instrument is used, it will be seen that several separate vesicles generally at first appear, that these, by and bye, coalesce, and that when the resulting scab falls off, one "mark" or cicatrix only remains. But this cicatrix, as we have said, may have a "foveated area" equal to that left by several separate vesicles following single punctures with a lancet. It will hardly be contended that the cicatrices in each case—those resulting from several vesicles which have coalesced and have left a single, large, typical "mark," and those resulting from a single vesicle, which leaves, also, a single, but smaller, typical "mark" indicate equal protective values.

5. *Fever.*—The ratio of deaths attributed to this disease decreased from 25·32 in the previous year to 22·99 during the year under report. Although, as Dr. Dyson says, the term "fever" covers a multitude of complaints in the minds of the registering agents, in the main, he thinks, it may be taken that the majority of the so-called fevers entered in the mortuary returns are of malarial origin. An examination of the fever map shows that, whilst there is more fever in the parts of the province which are made up of alluvial soil than in the portions of older formation, high mortality is by no means confined to the alluvial tracts. "It is, however, my decided opinion," the Sanitary Commissioner writes, "and, I believe, it is also the opinion of the majority of the local medical officers and of others "who have given the matter serious attention, that in Bengal malarial fever is, on the whole, "associated with the stoppage of natural drainage." Removal of this stoppage is obviously the remedy for this prevalence of malarial diseases; but a general system of drainage for a country of the size and physical conformation of Bengal may, for the present, be regarded as beyond the resources of any Government to carry out and maintain. The most that can be expected is an endeavour to improve the drainage of specially water-logged and unhealthy tracts. Even on this limited scale, the maintenance of the drainage in an efficient state in a country liable to frequent inundation with its resulting alterations in the features of the localities affected, would entail a heavy and recurring expenditure. We have still much to learn regarding the causation of the epidemic prevalence of malarial fever; and outbreaks of the disease, such as that from which Bihar suffered during late years, are deserving of special investigation.

6. *Sanitary Works.*—"Out of 23½ lakhs of rupees spent on sanitation (excluding roads)," it will be seen that, in round numbers, 2 lakhs and 74,000 rupees were spent on "drainage," 7 lakhs and 98,000 on "water-supply," and 3 lakhs and 31,000 on "treatment of the sick." The contrast of expenditure on so limited a scale with the sanitary needs of so great a province creates a sense of the inadequacy of the means to the end to be accomplished. Such sanitary improvements as have been recorded are mostly confined to municipal towns. Of the villages, Dr. Dyson writes:—"The reports "of the local officers do not show that any attempt was made during the year under report to effect "improvement in regard to village sanitation, and, as far as my limited experience of the province "goes, such a thing does not seem to exist in any form whatever."

19th July 1897.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the North-Western Provinces and Oudh for 1895.

Judged of by its vital statistics the year 1895 was one of the healthiest on record. Its death-rate of 29·13 per 1,000 of population is in striking contrast with that of 1894, which was 42·51. To some extent the low mortality of the year under report was doubtless the consequence of the high mortality of its predecessor. As we have remarked in another memorandum, an unhealthy year largely eliminates from the population the very young, the very old, and the constitutionally feeble, besides lessening fecundity and so reducing the birth-rate of the year following. Relieved of the portion of its population least capable of resisting sickness, and having its birth-rate, which always has a marked influence on the death-rate, greatly reduced, 1895, from these circumstances alone, might have been expected to show a lessened mortality. But, in addition, "there was no scarcity, and climatic conditions were favourable to health."

2. *Vital Statistics.*—The *births* exceeded the deaths by 270,792 ; whilst in the preceding year the deaths exceeded the births by 131,743. Although the year under report was exceptionally healthy, its birth-rate was much below that of 1894, which was exceptionally unhealthy, showing that, as might be expected, the birth-rate of a year is regulated not so much by its own health conditions as by those of its predecessor.

3. Of *deaths* there were 1,366,443 registered against 1,993,778 in 1894. That the registration of births and deaths in these provinces is, considering the agencies employed in carrying it out remarkly accurate, was strikingly shown by the last enumeration of the population in 1891. The population numbers got by adding to the census figures of 1881 the births registered in excess of deaths for the intercensal period 1881–90, were in 1890 found to be 46,842,838 ; and the population numbers got by the actual counting of the people in the following year, 1891, was 46,888,557. So close an approximation in results cannot fail to establish confidence in the efficiency of the system of registration in force. The Sanitary Commissioner is fully justified in saying :—"The collection of "statistics for this vast area and population is carried on by the village watchman, the only method "possible with any regard to reasonable economy, and, upon the whole, is wonderfully well "performed. Probably it is one of the most efficient reporting agencies, at the price, in the world." Inherently sound, however, as the system has proved itself to be, it no doubt owes its efficiency largely to the close supervision and check to which it is subjected by the local authorities and the Vaccination Establishment. Twenty-one per cent. of the births and 20 per cent. of the deaths registered in 1895 were tested by these agencies. In the testing done by the local authorities the percentage of admissions works out for the province at 2·78 per cent. in the case of births, and 2·64 per cent. in the case of deaths ; whilst, in the testing done by the Vaccination Department, the percentages are 1·46 and ·72 respectively for births and deaths. The Lieutenant-Governor concludes from these figures that the testing of the Vaccination Department would seem to be perfunctory. Before agreeing to such a conclusion it would be necessary to know what the system of testing by the two agencies actually was. As we have had occasion more than once to observe, no mere examination of the watchmen's handbooks and of the police registers can be regarded as an efficient testing of registration of births and deaths. This can only be effected by a house-to-house inquiry, and a comparison of the results so obtained with the entries in the handbooks or the registers. The process is tedious and laborious; but, so far as we know, it is the only one by which the actual facts can be got at. It has hitherto usually been found that the proportion of births omitted from the registers was considerably in excess of the proportion of the deaths so omitted ; and this the figures obtained as the result of the inquiries of the Vaccination Department would confirm, the proportion found by them being about two of the former to one of the latter. It may be, however, that the births of children more directly concern the vaccinators, and that, as a consequence, their registration is subjected to a more searching scrutiny.

4. *Chief Diseases.*—The returns show that there was a substantial decrease in the mortality under the head of each of these diseases. The number of deaths from *cholera* fell from a ratio per 1,000 of population of 3·80 in the preceding year, to 1·10 in the year under report. The year began badly, no fewer than 2,839 deaths from this disease having been registered in January alone. In no one of the previous 14 years for which statistics are given in the table on page 21 was the mortality from cholera so high in this month. December of the preceding year has recorded against it 7,349 deaths from cholera; so that the prevalence of the disease in the beginning of the year under report was not due to a fresh outbreak, but was merely a continuation of the epidemic of 1894. In February it appeared to be subsiding; but this appearance was delusive; it again increased in March and April, attaining its greatest intensity in May. After this it again decreased until November, during which, instead of subsiding, as it almost invariably does, it on the contrary suddenly increased, and caused more than twice the number of deaths attributed to it in the preceding month. In December it showed little sign of abatement. These peculiarities in the cholera history of the year are well brought out by the Sanitary Commissioner, who remarks :—"But for this "prevalence of cholera in the concluding months of the year, 1895 would have been a decidedly "healthy year as regards this disease." It is important to note the climatic conditions which accompanied this unusual recrudescene of cholera in November. "The principal meteorological "features of the year were the defective rainfall during the last four months of the year, and the

" abnormally high temperature prevalling in November." In paragraph 189 of his report, Dr. Thomson writes:—" The abnormally high temperature in November has been referred to. It is " probable that it affected the health conditions of the province, more particularly in retarding the " decline of cholera mortality in the eastern districts."

5. *Small-pox.*—The mortality from this disease was the lowest ever recorded in the province; there were only 1,968 deaths attributed to it, giving a ratio per 1,000 of population of 0·04. The table given on page 23 of the Report illustrates the gradual decrease of small-pox during the past 25 years. Not since 1890 has the mortality from this cause reached so high a ratio as 1 per 1,000 of the population. But rapid as the progress of vaccination in recent years has been, and decided as have been its protective effects, it would be a delusion to believe that epidemics of small-pox would no longer recur. The most that can be looked for is, that these recurring epidemics will be less violent. The influence of vaccination on small-pox prevalence is well put in the Orders of Government on the Sanitary Report:—" The disease has periods of advance and retrocession, but the table giving the " small-pox death-rates for the past 25 years at page 25 of the Report shows unmistakeaby that each " epidemic wave advances less and recedes farther than its predecessor." So long as the children under one year of age successsfully vaccinated number little more than a third of the number of births, small-pox is little likely to die out for lack of material to keep it alive. In the year under report three were 1,637,235 births registered; whilst 349,700 children died, leaving 1,287,535 available for vaccination. Of these last, only 570,002 were successfully vaccinated during the season 1895–96, leaving unprotected against small-pox 717,533. But whilst these figures show that infant vaccination is still backward, the figures for the group of children between one and six years show that the arrears of unprotected children remaining at one year of age have been largely overtaken within the next five years. Taking the vaccinations performed at all ages, these equalled 79·76 per cent. of the births. " This is a closer approximation to the birth-rate than has ever been attained before." We are glad to see an order issued to the effect that " hot weather vaccination operations " shall only be carried on when small-pox is present in any district in an epidemic form." The inexpediency of carrying on vaccinations in the plains during the hot season was almost from the first fully recognized by the Vaccination Establishment; but it was hastily concluded that in coming to this conclusion the vaccination staff might be biassed in favour of an arrangement which set them free from work in the plains, and found some of them employment in collecting vaccine lymph in the hills during the hot season of each year. Experience has shown that in this instance bias, if any ever existed, coincided with the safest and best method of carrying out the work of the Department.

6. *Fever.*—There was a marked diminution in the fever mortality in the year under report as compared with 1894. The ratio of deaths from this cause per 1,000 of population fell from 31·88 in the latter year to 23·31 in 1895. The beneficial effects of the drainage of water-logged tracts of country in lessening fever prevalence have been well exemplified in such districts as Meerut, Aligarh and Bulandshahr. It is an axiom in practical sanitation that, when a water-supply is introduced into a town, arrangements should be made for its removal after it has served its purpose. Similarly, when water for purposes of irrigation has been distributed over a tract of country, a system of drainage should be provided for the removal of the surplus water which would otherwise remain to water-log the soil, and generate or intensify malarial diseases. There is probably no exception to the rule that the health of a water-logged country is improved by efficient drainage.

7. *Sanitary Works.*—In no other province of India has so much progress been made in providing the larger towns with one of the first essentials of healthy life, a pure water-supply. Already the great cities of Benares, Allahabad, Cawnpore, Agra and Lucknow have their water-supply schemes completed; whilst other large towns, such as Meerut, Fyzabad and Farukhabad are either carrying out or considering similar schemes. The drainage works, which are the necessary complement of a water-supply, will tax the resources of those cities and towns for their completion, but completed they must be if the introduction of the water-supply is to prove an unmixed benefit to the public health. It is too early yet to look for decisive proof in vital statistics of the beneficial effects which ought to follow the substitution of a pure for an impure water-supply. The Sanitary Commissioner is of opinion that " in no town in these provinces do more than 75 per cent. of the inhabitants use " filtered water," the remainder still continuing to draw their supplies from the numerous and frequently polluted wells which abound within the inhabited area. Moreover, the beneficial effect of a pure water-supply will be to a measurable extent neutralized by the water and sewage logging of the soil which inevitably result from the introduction of water into a town without the provision of means for its effectual removal when it has fulfilled its uses.

8. The Government of India consider the notes on the sanitary conditions and defects of towns and districts given in the last four columns of Annual Form II. to be frequently of too general a character, and to refer to the district as a whole instead of to individual towns and circles separately. This is quite true; but when it is considered that there are no fewer than 1,392 towns and rural circles, some idea may be gathered of the magnitude of the task involved in furnishing a special description of the sanitary conditions and defects of each within the period fixed for the submission of the Annual Report.

19th July 1897.

No. 4.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Punjab for 1895.

During the year the meteorological conditions were more favourable to health than usual; the weather was milder, and the rainfall considerably below the average. This last-mentioned condition, however, although known to be directly conducive to lessened sickness and mortality from fever and bowel complaints, had an unfavourable influence on the crops, and so indirectly tended by raising the price of food to lower the disease-resisting powers of the poorer classes. The consequences of this rise in the prices of the ordinary articles of diet, and the resulting reduction in the stamina of the poorer classes, forming everywhere in India a large proportion of the population, would not at once be reflected in the statistics of mortality, unless the rise in prices were sudden and great. It is during the following year that both the birth and death-rate may be expected to bear witness to the effect of this rise in the price of food in 1895. From the table given in paragraph 30 of the report it appears that, whilst in 1894 one rupee would buy 23 seers of wheat, it would buy only 21 during the year under report, and that whilst in the former year it would buy 20 seers of the pulses in common use, it would buy only 14 seers in the latter year. As a slight set-off against this increase, the price of rice fell from 10 seers per rupee in 1894 to 11 seers in 1895. The Lieutenant-Governor, in paragraph 7 of his remarks on the report of the Sanitary Commissioner, points out that it was unnecessary to fill 4½ pages of print giving meteorological details for each month of the year, whilst at the same time omitting to draw any deductions therefrom as to the influence which the weather conditions exercised on the health of the Province. "The Government of India," he adds, "probably only wanted such observations on the weather and food prices as would really be of "some help in considering the causes of the recorded birth and death-rate. An undigested "statement of weather conditions and a table of prices does not help us." Thus simply stated, the probable object the Government of India had in view seems so obvious that the wonder is it could have been overlooked.

2. *Vital Statistics.*—As usual, the *birth-rate* of the Punjab is greatly higher than that recorded for any of the other provinces of India. In the year under report it was 43·86 per 1,000 of population, the North-Western Provinces coming next with only 34·90. This ratio would seem to speak well for the care with which births are registered in the Punjab, but the Lieutenant-Governor thinks it is not easy to say how far it is due to a better system of registration and how far to other causes. Excluding the small hill district of Simla, the circumstances of which are exceptional, the birth-rate varied from a minimum of 34·8 in the Kangra district, to 54·4 in the Gujranwala district. Yet, comparatively high although the ratio of the Province is, there are good reasons for believing that if all the births had been recorded it would be considerably higher. When we compare the proportion of the sexes born, we find, for the province as a whole, that for every 100 births of female children there were 110·6 births of males recorded. This proportion may, of itself, be taken to indicate the omission to register a considerable number of the births of females. Selecting some of the frontier districts, we find the incredible proportion of 141·4 male to 100 female births in the Peshawar district, and of 128·9 to 100 in the district of Dera Ghazi Khan. The divergence in the recorded numbers of the sexes born may pretty safely be assumed to increase with the inaccuracy of registration, and to lessen as improvement takes place. In our memorandum on the report of the Sanitary Commissioner of Bombay for 1894, we remarked:—"As in the case of his birth, so likewise "as regards his death, a male is held to be of more importance than a female, and the registration "of either his birth or his death is less likely to be omitted." The Lieutenant-Governor in paragraph 3 of his remarks alludes to a more serious cause for the omission to record births of female children in certain districts of the Province. In his opinion the result of inquiries proves beyond a doubt that "female infanticide, using the expression in the wider sense as including also mere "deliberate neglect of female infants, still prevails to a most lamentable extent" among certain classes. In addition to the reasons we have given for believing that all of the births are not registered, we have direct evidence in support of this belief. During the year, the Sanitary Commissioner, two Civil Surgeons and the Vaccination Staff, together with some of the tahsildars and their assistants, discovered the omissions from the registers tested by them of 27,244 births and 11,182 deaths. As but a small proportion of all of the registers could have been examined by these officers, it may be concluded that from the registers of the Province as whole, the births and deaths omitted must have amounted to a total which would materially affect the accuracy of the returns.

3. Under the healthy climatic conditions which characterized the year, the *death-rate* was only 29·29 per 1,000 of population, as compared with 36·32 in the preceding year. There was no unusual prevalence of epidemic disease, and there was a marked diminution of fever mortality. According to sex there were 112 deaths of males to every 100 deaths of females, whilst, according to age, the death-rate of male children under one year of age was 218·05 per 1,000 of population to 210·14 of female children of the same age. Judging from the number of persons punished in the 151 municipal towns of the province for failure to register births and deaths, the byelaws are, as the Sanitary Commissioner says, a dead letter in many of these towns. Those fined for neglect of registration numbered 117, and the fines amounted to a total of 99 rupees. The Sanitary Commissioner is confident, however, that the agencies now at work in checking the registers of mortuary statistics will before long make registration as perfect as can be expected. But, as we remarked in the second paragraph of our memorandum on the Report of the Sanitary Commissioner of the Hyderabad assigned districts, inspection of registration to be effective must be thorough. Examination of registers, conducted as described in paragraph 24 of the Report, is worse than useless,

inasmuch as it encourages neglect by conferring on those guilty of it a sense of security that they will not be found out. In the registers of as many as 564 villages inspected by tahsildars and their assistants there was only one omission discovered in the birth, and one in the death register. Such inspection Dr. Roe describes as a "mere farce."

4. *Chief Diseases.*—During the year under report, as during its two predecessors, *cholera* prevailed to only a slight extent. There were, altogether, 549 deaths registered from this disease, equal to a ratio per 1,000 of population of only 0·03. Compared with the other chief diseases, cholera plays an unimportant part as a cause of mortality in the Punjab. Only in three of the last 29 years has the death-rate from it reached one per 1,000 of the population; and it is significant that in two of those three years there was a *kumbh-mela*, or great bathing fair at Hardwar. The Punjab invariably sends a large contingent of pilgrims to these fairs; and, when epidemic cholera breaks out in the vast multitude assembled at Hardwar, numbers contract the disease and carry it back with them to their own country. The last great epidemic in the province occurred in 1892, which was not itself a *kumbh-mela* year, although immediately following one. During 1895 the disease was chiefly confined to the Umballa district; in fact, 511 of the 549 deaths caused by it took place in that district alone. Particulars of the outbreaks of the disease in the Umballa district are furnished by Assistant Surgeon Alla Dita, who inquired personally into the matter. It is difficult to believe that the Sanitary Commissioner expects the Assistant Surgeon's evidence to be accepted as sufficient proof of the importation of cholera. A man, we are told, came from Rajpura, in the Patiala State, to the village of Chunian Khurd, was attacked at the latter place with cholera symptoms on the 19th April and died on the 22nd April. This case was reported in the Chaukidar's death register as a case of fever, but, after "careful inquiry made by me," writes the Assistant Surgeon, "I am of opinion that Kirpa "Ram, who came from Rajpura, brought the disease with him. Cholera was prevailing there in "epidemic form for the past month." It would appear that the Assistant Surgeon did not himself see the case, and that the evidence afterwards obtained by him as the result of his inquiry consisted merely of what the villagers could tell him about it. Even the date on which the inquiry was made is not stated. The next five cases of cholera following the supposed death of Kirpa Ram from that disease on the 22nd April took place on the 28th of the same month. "These cases occurred in the "vicinity of Kirpa Ram's house." On the 29th of April five more cases occurred. "In my opinion," writes the Assistant Surgeon, "the well in the village of Chunian Khurd, from which the "water-supply was obtained, was contaminated, which is the cause of the spread of the disease. "It is a common practice in the villages to bathe on the side of a well, and to wash their clothes "on the same spot; in this way the water-supply is contaminated. In Chunian Khurd the "contaminated well was closed about the 30th April 1895, and the water was then obtained from "wells situated at about 200 yards distant from the village. After stoppage of water-supply from "contaminated well the disease disappeared." The statement is so illogical and rests so entirely on opinions and assumptions, not on exact facts, that it would not have been noticed by us but for the circumstance of its being apparently accepted by the Civil Surgeon as conclusive proof of importation of cholera into the Umballa district. Dr. Young, in forwarding the above particulars, writes:—"The epidemic in this district thus imported began at the village of Chunian Khurd," &c. It is instructive to contrast this case of assumed importation of cholera into a village with the account of the appearance of the disease in five jails given in our Memorandum on the Report of the Sanitary Commissioner of the Central Provinces. Although these jails were under the constant supervision of medical officers, yet the most careful inquiry on the spot and at the time the disease first showed itself left it doubtful as to how cholera found entrance into any one of the five.

The system of attempting to disinfect wells, the water of which is suspected of communicating cholera, was practised in the Umballa district. The Lieutenant-Governor subjects the account given of the results to a careful judicial examination, and shows very clearly that experiments of the nature described will have to be conducted with more regard to scientific method before safe deductions can be drawn from them.

5. *Small-pox* is credited with having caused 8,334 deaths during the year. Of this number, 2,442 occurred amongst children under one year of age; whilst of children under 12 there were altogether 7,686 deaths. These figures point to neglect of vaccination of young children; and the existence of such neglect is abundantly proved by the inquiries of the Civil Surgeon of Umballa.

In the frontier districts, outbreaks of small-pox are stated to have been caused by the operations of inoculators; and it is proposed to endeavour to induce these men to give up the practice of their own craft and become vaccinators. Experience in other provinces has shown that converted inoculators rarely become good vaccinators. Their former calling was so much more profitable, and carried on under conditions so comfortable and congenial, that many of them were found to clandestinely revert to it, especially during the hot season, when risk of detection was least. They find the lot of the vaccinator, urged on by his superiors to continual exertion, and often opposed and rudely treated by the parents of children whom he must vaccinate without reward, by no means an enviable one.

The record of vaccination for the season 1895–96 is a good one. There were 645,846 primary cases returned as successful, against 616,456 in the previous year, giving a percentage of success of 93·10, as compared with 93·75 in 1894–95. Of the total successful primary vaccinations 487,217 were performed on infants under one year of age, and 153,692 upon those of over one and under six years. The appointment of six Divisional Inspectors affords an additional guarantee of the accuracy of the recorded work. Increased vigilance and strictness on the part of the supervising staff have caused some decrease in the percentage of cases recorded as successful; but there has doubtless been a corresponding decrease of "returns falsified, and children returned as successfully vaccinated when

" they were not." The practical test of the efficiency of vaccination is its influence in preventing small-pox; and if we turn to the table given in paragraph 31 of the Sanitary Commissioner's Report we find a marked diminution in the mortality from this disease in the Punjab during the past 29 years which the record covers. During the first seven of those 29 years the mortality never fell below 1 per 1,000 of the population, and during one of them was over 3. During the last 16 years the mortality from small-pox never reached 1 per 1,000, and has generally been less than half of this.

In the year under report 93 per cent. of the operations were performed with buffalo lymph; but the increasing difficulty of obtaining buffalo calves has been found to be a great hindrance to progress. Dr. Roe believes, however, that he has at length succeeded in overcoming this difficulty by substituting preserved for fresh lymph. The method adopted for the preparation of this preserved lymph is that practised in Berlin, "with the exception of vaseline being used as the vehicle for the vaccine instead " of glycerine."

6. *Fever.*—The deaths attributed to fever were fewer than during the preceding year by no less a number than 123,120. Yet did the death-rate from this cause in an exceptionally healthy year reach the high ratio of 19·08 per 1,000 of population. A special report has been called for by the Government on the question of fever prevalence in the Province; and the Sanitary Commissioner states that he is collecting the materials necessary for its preparation. "The Lieutenant-Governor " trusts he will receive at least an instalment of this report before long, and that it will help us to " get beyond the region of vague generalities and conjectures." After all, cholera, to the investigation of which so much attention has been given, is in the Punjab an altogether trifling cause of sickness and mortality when compared with fever. While the deaths attributed to cholera during the year numbered 549 those attributed to fever numbered 392,118.

7. *Sanitary Works.*—Of these it is stated that the list, " both completed and contemplated, is as " satisfactory as can be expected under existing financial conditions." With the opinion expressed by the Lieutenant-Governor, that, in considering schemes for the better sanitation of villages, attention should be concentrated on the water-supply, we cordially agree. The improvement of the water-supply is a clear and definite object which, if carried out, no one doubts will be followed by marked benefit to the public health. As yet few of the villages possess an abundant supply of pure water, universally acknowledged to be one of the finest conditions of healthy existence. The expenditure needful to secure it would, the Lieutenant-Governor states, " absorb all the funds we " are likely to have available for some time to come." These funds, we feel sure, could not possibly be more usefully expended in the interests of the health of the people of the province.

8. An examination of Annual Form No. II., extending over 83 pages, leads us to ask whether it is worth the time and labour expended in its preparation and the cost of printing. For some of the districts the important column headed "Measures taken for sanitary improvement of Circle" is entirely blank. We may quote as examples the districts of Lahore, Jullundur, Gurdaspur, and Peshawar. Under the heading of "Principal Defects of Circle in Water-supply" we find for an entire district the one word "None" recorded. As examples we may mention the districts of Dera Ismail Khan and Gurdaspur. It is nearly the same with regard to the remarks on "Drainage" and " Domestic cleansing and Conservancy." Very different, however, is the "Statement showing the " Conditions of Municipal Towns as regards Water-supply and Drainage in the 1st, 2nd, and " 3rd Circles, Building and Roads Branch, Punjab Public Works Department." The information given in this statement is evidently carefully collected and might be turned to useful account.

19th July 1897.

No. 5.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1895.

This Report is of a somewhat meagre and fragmentary nature. Of the ten sections into which the prescribed form of sanitary report is divided, only Sections V. and VI., relating to Vital Statistics and Chief Diseases, are dealt with in anything approaching to adequate completeness. The general history of vaccination is given in a separate report. Regarding the climatic features of the year no remark is made. The section on sanitary works is entirely devoted to a statement of the sums of money expended on these works. Of the 39 pages of which the report consists, excluding the appendices, no fewer than 25 are entirely covered by tabular statements, and of the remainder many are to a large extent similarly filled up. Consequently we are mostly dependent on the resolutions by the Chief Commissioner for an account of the sanitary and vaccination work of the year.

2. *Vital Statistics.*—To Lower Burma only, with a population according to last census of 4,516,599, do the remarks on vital statistics and chief diseases refer. Into Upper Burma, excepting in the case of four towns, registration of births and deaths does not appear to have yet been introduced. During the past year the number of *births* registered exceeded those of the previous year by 6,394, and was equal to a ratio per thousand of population of 29·04, as compared with 27·62 in 1894. The ratio was the highest hitherto recorded. In paragraph 5 of the report the provincial birth-rate is shown for the past 24 years. In 1872 the recorded rate was only 17·79, and even so recently as

1891 was only 20·74; but since the latter year there has been marked improvement in registration. The system of registration in force in Burma is described in the Appendix to the Report. The duty of reporting births and deaths is imposed on the headman of a village, and the collection of records on the police. If both agents acted up to the instructions issued for their guidance, the registration of vital statistics in Burma would soon cease to be characterized as the "worst in India." But unfortunately neither the headmen nor the police appear to carry out this part of their duties with much efficiency. In one village in which the headman had recorded only 10 births during the year, the Civil Surgeon saw at least 50 children under one year of age. The same Civil Surgeon when on tour in the Pegu district, discovered that 1,072 birth and 864 death foils, collected from village headmen by the police, had not reached the Deputy Commissioner's office. What strikes us as a weak point in the rules is the want of some definite arrangement for the charge of the village register during the occasional absences of the headman. He is ordered when he leaves his village to deposit the foils already collected with a village elder or some other responsible person, who will make them over to the police if they should call during his absence. It is left to each headman to make his own arrangements as to the custody of the register, and also, it may be concluded, for the entry in it of any births or deaths occurring in the village before his return. The agent he selects might or might not fulfil the headman's instructions. Unless he were paid, or under some authoritative obligation to do so, it is improbable that he would trouble himself much about the duty entrusted to him. The result would be that some of the births or deaths would probably go unrecorded, or the foils remain undelivered to the police when the latter visited the village. The police, on the other hand, being paid and under discipline, neglect of their duties in connection with the collection of the foils of births and deaths could be dealt with in a way calculated to impress them with the need for exercising proper care. The Chief Commissioner says it is hardly necessary to point out that ample powers have been conferred by law to punish persons who neglect to report births and deaths as well as those who neglect the duty of registering and transmitting such reports.

3. The number of registered *deaths* fell from a ratio of 23·56 per 1,000 of population in 1894 to a ratio of 22·40 in the year under report. It is admitted that the general average for the province can hardly be regarded as even approximately correct. Confining our examination to a statement, covering nearly ten pages, "showing the number of births and deaths registered during the year 1895 "in those circles in which experience has shown that the returns are compiled with some approach to "regularity, and that the figures are on the whole fairly reliable," we find the recorded number of deaths varying from zero in Kyao to 106·94 in Pyingyè. In the same statement birth ratios of from 5·62 to 97·03 are met with. We agree with the remarks made by the Chief Commissioner regarding the value of this statement, when he writes:—"The grounds for the opinion of the district officers "that registration is less faulty in these 'selected' circles than in the province generally are not "stated, and in most cases are difficult to understand. The Officiating Chief Commissioner does not "think that any advantage is gained by the preparation of such a statement as that printed on pages "2 to 11 of the report." With the object of improving the registration of deaths in towns, a proposal was submitted by the Sanitary Commissioner to the effect that a certificate of registration should be required before bodies are permitted to be buried or cremated. Doubtless this would be an effectual means of bringing about improvement in registration, but if it tended to delay the burial or cremation of the dead, as seems likely, the improvement might be purchased at too great a cost to the public health. The Government of India call attention to the absence of all mention of the infliction of fines by municipalities for neglect to report births and deaths. Unquestionably there are in Burma special difficulties in the way of effecting accurate registration of vital statistics, but if supervision were more strict and constant, improvement would follow, as it has been found to follow such supervision in the provinces of India. Their knowledge and opportunities specially fit officers of the medical and vaccination establishments for efficiently assisting the other district officials in supervising and checking registration.

4. *Chief Diseases.—Cholera* caused, according to the returns, 5,150 deaths, as compared with 7,428 in the previous year. The disease prevailed in all districts, and from most of the divisions of the province was absent during no month of the year. The Sanitary Commissioner cautions us against probable error in diagnosis on the part of the ignorant agents entrusted with registration. He gives instances in which outbreaks of cholera were reported, which on inquiry by medical men were found to have no existence in fact; and he justly regards with scepticism the dates and localities assigned to the appearance of first cases in the rural parts of the province. There are other provinces besides Burma on the cholera returns from which just as little reliance can be placed as regards the dates assigned to first cases of the disease. It is certain that mild cases of cholera are frequently reported as cases of diarrhœa or dysentery, and equally certain that when the disease has once been recognised and reported as prevalent in any locality, nearly every form of bowel complaint is thereupon frequently returned as cholera. The Sanitary Commissioner writes:—"Several medical officers "in reporting on cholera, declare their inability to say whether the disease was, or was not, imported. "It is a significant fact, however, that cholera had broken out in several towns during the hottest "months of the year, just before the setting in of the rains, when scarcity of water was most felt, "owing to wells running dry and yielding muddy water."

5. *Small-pox.*—The number of deaths attributed to this disease during the year was 1,540, or ·34 per 1,000 of population. Of these deaths 890 occurred amongst children under 12 years of age; and of this number 348 were under one year of age. The backwardness of vaccination amongst infants, which may be deduced from these figures, is further shown by an examination of the returns in the Separate Vaccination Report. The recorded number of births in Lower Burma in 1895 was 131,147; and deducting from these the number of deaths which occurred amongst children under

one year of age, there remained available for vaccination 109,158. But the number of children under one year of age who were vaccinated during the season 1895–96 was only 41,107, leaving unprotected against small-pox 68,051. Until, therefore, the number of infants annually vaccinated approaches more nearly than at present the number available for vaccination, a high proportion of the deaths from small-pox may be expected to continue to occur amongst young children. Rapid progress in the extension of vaccination is, however, taking place. Within the last four years the number of successful cases of primary vaccination in Lower Burma has nearly doubled, having increased from 101,540 in 1892–93 to 196,536 in 1895–96; and the proportion of successful cases per 1,000 of population from 25·79 in the former season to 44·89 in the latter. Progress has been scarcely less satisfactory in Upper Burma. Accompanying the increase in the numbers vaccinated, an increase in the percentage of successful cases in primary vaccination is a satisfactory feature of the returns. This percentage is now 91·2. On the other hand, the number as well as the percentage of successful cases of re-vaccination has diminished. As the Chief Commissioner correctly observes:—"A falling-off in "re-vaccinations, properly so called, is no matter for regret. It is desired that vaccinators should, as "far as possible, confine their energies to primary operations until they have overtaken the annual "increase of the population by births, and this goal is far ahead except in the large towns."

6. *Fevers* are credited with having caused 48,049 deaths out of a total from all causes of 106,407. Excepting during the preceding two years this is the highest number of deaths from fevers on record. It should not, however, be lost sight of that the annual increase of the population of Burma, which during the ten years between 1881 and 1891 amounted to 22 per 1,000, would to an appreciable extent account for the greater number of deaths from fevers as well as from other diseases. There can likewise be no doubt that, owing to greater attention to registration, more deaths are recorded in recent years from all causes, fevers included, than in former years. An examination of the table given in paragraph 5 of the Report shows a rise in the recorded number of deaths from 33,239 in 1872 to 106,407 in 1894. An increase by which the deaths have been more than trebled could hardly have been due to greater unhealthiness of the province, and was more probably the result of greater care in recording deaths, as well as to an increase of these proportionate to the growth of the population since 1872.

7. The mortality from *diarrhœa and dysentery* was the highest on record. This, however, the Sanitary Commissioner attributes, not to the unhealthiness of the season, "but to more accurate "classification." The causes which we have suggested to account for the increased number of deaths recorded as due to fevers must also have contributed to a similar increase in the recorded number of deaths from diarrhœa and dysentery.

8. *Sanitary works.*—Some 20 lakhs of rupees were expended during the year on "works designed "directly or indirectly for the maintenance and improvement of the public health;" but no sanitary work of first-class importance was undertaken. Schemes for providing the towns of Moulmein and Mandalay with water supplies have been prepared, and the question of providing the funds necessary for their execution is under consideration.

No. 6.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Central Provinces for 1895.

The masterly analysis to which the report has been subjected in the Chief Commissioner's Resolution leaves little for us to add. From a climatic point of view the year was healthier than its predecessor, a result credited to deficient rainfall and consequent decrease in the fatality of fever. But if the deficiency of rain was conducive to lessened fever prevalence, it was, on the other hand, the cause of scarcity of good drinking water, and the concomitant diseases of such scarcity, cholera and bowel complaints. A series of bad or poor harvests during preceding years was followed in 1894, and in the cold weather of 1894–95, by still worse. "Thus," writes the Secretary to the Chief Commissioner, "the mass of the population over a large part of the province suffered during "the year 1895 from want of food, or eked out a subsistence with inferior and unwholesome articles "of diet." What, therefore, from a climatic point of view, should have been a healthy season, became, under the pressure of a deficiency of wholesome food, a season of great mortality. A year, such as 1894 was, of exceptionally great mortality is usually followed by one of low mortality, partly, no doubt, because such a year proves fatal to a large proportion of the very young, the very old, and the constitutionally feeble, and thus weeds the population of those least capable of resisting disease. But, according to the Sanitary Commissioner, "excluding the effects of epidemic influenza, "and allowing for the lessened fatality from fevers, it is certain that last year was even yet more "unhealthy than its predecessor, and therefore the worst of any year, excepting 1889, within the "last 10."

2. *Vital statistics.*—The *birth-rate* was the lowest recorded within the last 15 years, and was only 33·41 per 1,000 of population as compared with 38·82 in the preceding year. Excepting in four out of the 18 districts, a decrease in the number of births was noted. That the decrease was a real

one, and not due to a falling-off in registration, is beyond question. The sickness and mortality accompanying the privations of 1894 doubtless produced their usual effects in diminishing the fecundity of the people during the year following. To such an extent was this the case that the excess of births over deaths, which in ordinary years is normal, was converted into an excess of deaths over births. Whilst the birth-rate was 33·41, the death-rate was 36·75 per 1,000 of population; and, as predicted by the Chief Commissioner, "it is to be feared that the current year "(1896) will likewise show a falling-off in births, the series of bad harvests not having yet been "broken by a cycle of prosperity." Saugor district may be taken as an example of the influence which the unfavourable conditions described exercise on fecundity. In this district less than half the number of births were registered in 1895 that were registered in 1894. Without doubt defective registration is to some extent accountable for this deficiency of recorded births. During seasons of excessive sickness the village watchmen suffer like their neighbours, and those living in distant villages are frequently unable from sickness to make their periodical visits to the police stations for the purpose of reporting the occurrence of births and deaths.

3. As usual, fewer *deaths* than births escaped registration, and this might to some degree explain the excess of deaths over births; but the reduction of the vitality of the population, owing to hard times, acting in the direction of reduction of number of births, and the greater prevalence of disease acting in the direction of increase of deaths, were mainly accountable for this abnormal result. Figures are given to show that, even when domestic occurrences were duly reported by the village watchmen, these, in a considerable number of cases, failed to be entered in the register owing to the carelessness of the clerk at the police station. The employment of Superintendents of Vaccination for the check of the village watchmen's registers has also led to the discovery of many unrecorded births and deaths. As the outcome of such examination, it appears that nearly twice as many births failed to be registered as deaths.

4. *Chief Diseases.*—The deaths from *cholera* were more more than double the number recorded in the preceding year, and were equal to a ratio, per 1,000 of population, of 1·63 as compared with a ratio of 1·56 for the previous five years. The disease prevailed in every district and in every month of the year. Some of the Civil Surgeons give evidence to show that cholera was imported into their districts. As usual, the evidence is inexact or incomplete, as, in the conditions under which it is obtained, it must ordinarily be. Five jails reported cases during the year. In these, if anywhere, the exact facts should be available; yet in none of the cases could importation be traced. In two of the jails, only a single case occurred in each. In one of these the prisoner had been five and a half months in jail, and had enjoyed excellent health up to the date of his seizure by cholera; in the other the prisoner had been five months in jail, and was employed at the time of his seizure as an attendant upon a patient in hospital. In the former case, "the exact mode in which it "(cholera) obtained admission was not discovered." In the latter, the Civil Surgeon thinks "the "disease was probably imported in food"; but he gives no evidence in support of this suggestion. In the other three jails in which the disease appeared, the remarks are respectively, "no connection "with previous cases outside could be traced"; "the Civil Surgeon is unable to say how the "infection was introduced"; and "the disease is supposed to have been introduced from outside, "but how exactly is not shown." We have thus five groups of people under the constant observation of scientific experts, and yet cholera appears in each group without its having been found possible to trace the cause of its appearance. We may well hesitate, therefore, to accept the confident assertions made regarding the importation of the disease into villages or into fairs, such assertions resting in most cases on statements obtained from ignorant villagers or village watchmen.

5. Mr. Hankin's plan of disinfecting wells with permanganate of potash was carried out at various places on the appearance of cholera. Regarding these experiments Dr. Newman says:—"Before "accepting the efficacy of the permanganate of potash process, we should have the facts established, "that the poison was present in some particular source of drinking water; that the people using "that water and in consequence of doing so were attacked by the disease; and that on addition "of the remedy the infection was destroyed. No such complete chain of proof has so far been "produced."

6. *Small-pox* was unusually prevalent, and accounted for 6,644 deaths—equal to a ratio, per 1,000 of population, of 0·70 as compared with 0·15, the average for the previous five years. As usual, children under one year of age suffered severely; amongst them, 2,019 deaths occurred. Yet, if we refer to the Report on Vaccination for 1895–96, we do not find that infant vaccination has been neglected. Of the total number vaccinated, 209,137 were children under one year of age: the registered births for 1895 numbered 317,432; and deducting from this number 97,583 deaths of infants under one year, there remained available for vaccination 219,849. The unvaccinated residue consequently numbered only 10,532; and during a season of privation and sickness it is more than probable that the health of a majority of these unfitted them for undergoing vaccination. In view of the decrease in the number of births and of the prevailing unhealthiness of 1895, a decrease in the number of vaccinations was only what might have been expected. The falling-off amounted to 31,379 cases, excluding the Feudatory States. In these latter there was a considerable increase. The recorded percentage of success attained in primary vaccination was 95·88. It is suggestive that, as the result of their inspection of the season's work, Civil Surgeons found of the cases examined by them only 87·62 per cent. to be successful. Animal lymph was exclusively used in some districts; whilst in others humanized lymph was mostly employed. Selecting one of the former, Narsinghpur, for comparison with one of the latter, Sambalpur, it would not appear that animal lymph always gave so high a percentage of successful cases as humanized lymph. According to Statement I., only

96·77 per cent. of the operations in primary vaccination were successful in Narsinghpur; whilst in Sambalpur 99·00 were successful. The latter percentage is, however, suspiciously high.

7. *Fevers*, although less fatal than during the preceding year, accounted for nearly two-thirds of the total number of deaths. A very instructive table, on page 24 of the Report, gives the ratios of deaths from fevers and other diseases, founded on the inquiries made by the Civil Surgeons, and contrasts them with the ratios given by the police in nearly an equal number of cases. The general result is that, whilst of 15,194 deaths Civil Surgeons found a ratio of 49·03 due to fever, the police found of 15,387 deaths a ratio of 59·98 due to the same cause. As might have been anticipated, in the great majority of districts the proportion of deaths ascribed to fever by the police was higher than the proportion so ascribed by Civil Surgeons; but in a few districts, such for example as Balaghat and Sambalpur, it was otherwise, and the proportion was equal to, or less than, that resulting from the inquiries of the Civil Surgeons. Regarding the 10 cases of enteric fever diagnosed in the Nagpur jail, Dr. Newman writes:—"Careful inquiry failed to trace any certain origin to the "disease in the conditions under which the prisoners were placed, or in their food supplies. The "drinking water, which is obtained from the Ambajheri Reservoir, was examined by Mr. Hankin, "who reported that he has found in it a bacillus 'resembling the typhoid bacillus,' but the same "water is used by nearly the entire population of Nagpur, by all the European residents, by the "many children in the numerous schools, and outside the jail only a few cases were seen. Had the "water been the cause, very many more people would almost certainly have been affected."

8. The poverty and hardship from which the people suffered, as the consequence of a succession of bad harvests, tended largely to raise the death rate from *diarrhœa* and *dysentery*. But, high as the recorded death-rate from these diseases is, it is certain that it is much under-stated. One Civil Surgeon remarks that the people seldom admit dysentery as the cause of death, and another says that many cases occur that are not shown in the registers. Both are, in Dr. Newman's opinion, correct.

9. "The larger *sanitary works* undertaken, or in progress, during the year are, as usual, all in "connection with the water-supply." Important as the provision of an abundant supply of pure water is for the towns, of scarcely less importance is its complement, a drainage system for the removal of the water when it has fulfilled its uses. Both of the chief cities of the province are provided with water services, but neither has as yet been able to find the funds necessary for carrying out drainage works. The cities of Bombay and Calcutta furnish examples of the disastrous consequences arising from the introduction of water into a town without suitable provision being made for its removal. In both cities the soil has become water and sewage logged to a degree which goes a long way towards neutralizing the beneficial effects on health of a supply of pure water.

19th July 1897.

No. 7.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Assam for the year 1895.

1. Although, in accordance with instructions, the inclusion in the report of the statement comparing the fluctuations of weather, of prices of food-grains, and of death-rates has been discontinued, it was not intended, as the Government of India point out, that the matter should be lost sight of in the Annual Sanitary Reports; and we are glad to see the request made that in future this subject may be discussed in the body of the report. Except that the monthly rainfall is shown in the tables recording the monthly mortality from cholera in each district, the climatic conditions which prevailed in the province during the year are not touched upon. Judged of from its vital statistics, 1895 was not so healthy as its predecessor.

2. *Vital Statistics.*—Whilst the *birth-rate* fell from 31·10 in 1894 to 31·00 in the year under report, the *death-rate* rose from 30·69 in the former to 33·72 in the latter. We have an opportunity in this report of comparing the results of registration of births and deaths carried out in several different ways. *Firstly*, in the Surma Valley districts, with a census population of 2,522,135, births and deaths are reported by paid village chaukidars. This system seems to be identical with that in force in the North-Western Provinces and elsewhere. In the Surma Valley the ratio of births thus recorded, per 1,000 of population, was 33·74; that of deaths 33·62. *Secondly*, in the Brahmaputra Valley districts, with a census population of 2,449,782, births and deaths are reported by unpaid *gaonburas*, with the result that the ratio of registered births was only 28·47, and of deaths 28·40. *Thirdly*, in nine sadr and 11 sub-divisional towns, with an aggregate population of 105,431, registration of births and deaths is compulsory. In these sadr towns the ratio of registered births, per 1,000 of population, was 20·80, and in sub-divisional towns 31·20; whilst the ratio of recorded deaths in the former was 28·87, and in the latter 43·47; dispensary deaths being excluded in both cases. *Fourthly*, in the hilly parts of the province, with a population of 455,749, registration was not carried out, excepting in certain selected areas with an aggregate population of 49,167. The ratios of births and deaths in these selected areas were, of the former, 25·79; and of the latter, 22·76. Obviously, the best results were obtained in the Surma Valley, where vital statistics are reported by paid village chaukidars. It might have been anticipated that in the 20 towns in which registration was compulsory, and taking into account the greater intelligence of their inhabitants as compared

with the rural population, the best results would have been attained; but in all except five of these towns the results were more unsatisfactory than in rural tracts were registration is not compulsory. The comparison between the different methods of collecting vital statistics in Assam would seem to suggest that, as far as practicable, the agents found to be most efficient, the paid village chaukidars, should be generally employed in the work of reporting births and deaths. Regarding the combined results obtained by the different methods described, Dr. Stephen remarks:—"There is little doubt "that in 1895 not less than 30 per cent. of the births in this province were not registered." As usual, deaths have been more accurately recorded than births; but even of these the Chief Commissioner, in his review of the report, estimates that about 19 per cent. escape registration. The normal birth and death rates of the province are estimated at 48 and 42 per 1,000 of the population respectively.

3. Dr. Stephen points out that the ratio of male to female births recorded affords some indication of the accuracy or inaccuracy of the registration. For example, in the Surma Valley, where registration, as we have shown, is carried out with comparatively greater accuracy than in other parts of the province, the ratio of recorded male to female births was 106 of the former to 100 of the latter. In the Brahmaputra Valley, on the other hand, where registration is most defective, the ratio of male to female children born was 109 of the former to 100 of the latter. This divergence in the proportion of male to female children born has been observed in other provinces to increase, as a general rule, with the inaccuracy of the registration—the greater the divergence, the more defective the registration.

4. Taking into account the ignorance of the agents employed in the collection of vital statistics and the fact that many of them are unpaid, approximate accuracy in the registration of births and deaths is all that need be looked for. Even this cannot as yet be said to have been attained; although with the object of impressing upon them the need for greater care, no fewer than 1,211 chaukidars and *gaonburas* were punished for neglecting to report births and deaths during the year, in addition to 192 persons prosecuted "for failing to report vital occurrences" in the circles in which registration was compulsory. Besides this, "in order to draw the attention of district officers "to defects in the returns furnished, when the monthly returns of vital statistics showed results very "much at variance with those of the corresponding month of the previous year, statements were sent "to them comparing the numbers furnished for the registration circles in question for the two years, "with the request that the matter might be inquired into, and that, if the differences were found to "be due to defective registration, corrected returns might be furnished." This appears to us to be "a more practical way of dealing with defects of registration than the publication of pages upon pages of figures showing the numbers of births and deaths recorded in each individual registration circle of a province, in the hope that the district officers may find time to examine the returns for the different circles and pass orders on them when they appear to be inaccurate. With such figures, in the previous year's report for the North-Western Provinces, no fewer than 159 pages were covered. The time and labour spent in the preparation of these returns for Bengal have not unnaturally drawn a remonstrance from the Sanitary Commissioner of that Province in his Annual Report for 1895. Another, and perhaps the most effectual of the means taken to improve registration, is inspection of the registers by police officers. In this work of inspection, assistance might be given by Civil Surgeons whilst on tour, and by the vaccination staff. A house-to-house examination only will definitely show whether the entries in the registers correspond with the births and deaths which have actually occurred. Dr. Stephen gives in his report short statements of the ratios of births and deaths from the statistics of other provinces for comparison with those of Assam. Such comparisons are very useful and might be made more frequently in the sanitary reports for other provinces.

5. *Chief Diseases.*—Although *cholera* was more fatal than during the preceding year, the number of deaths caused by it was less than the average for the five-year period 1889–93. The disease prevailed during each of the 12 months, and no district was exempt from it during the year. In some of the districts, such as Kamrup and Darrang, the death-rate from cholera was very high, a ratio of 8·14 having been recorded in the former, and of 6·73 in the latter, as against an average ratio, per 1,000 of population, of 3·78 for the province as a whole. In sadr towns the average ratio was higher than the provincial average, having been 5·36 as compared with 3·78 for the latter. In some of the towns this average was greatly exceeded. In the town of Tezpur the ratio of deaths was 13·46, and in Dibrugarh 10·63. The Sanitary Commissioner writes: "As cholera does not appear in "epidemic form in places in which the water-supply is properly protected, this high death-rate "shows that much remains to be done in the way of providing a protected water-supply for the "sadr towns of the province." Judged by this rule, it is feared that there is, as yet, no town in India with a properly protected water-supply, seeing that there is none which can be shown to be exempt from epidemic cholera. Even when measures are taken to provide a pure water-supply, Dr. Stephen gives instances in which the people perversely refuse to use it, and persist in taking water from sources known to be impure. The statement made regarding the greater prevalence of cholera in tea gardens hardly seems to bear out the conclusion that cholera prevalence varies directly as the purity or impurity of the water-supply: "The arrangements for protecting the "water-supply of many tea gardens are very efficient, and in almost all cases they are much more "efficient than the arrangements in villages, and as the other sanitary arrangements in tea gardens "are distinctly better than they are in rural tracts, the cholera rate ought to be lower in tea "gardens than it is amongst the rest of the civil population." The Sanitary Commissioner suggests a theory for the explanation of this refusal of cholera to fit in with the assertion that the disease does not appear in epidemic form in places in which the water-supply is properly protected. "The

" excessive death-rates from cholera in the gardens," he says, "is probably due to the fact that " the disease is at times introduced into gardens by recently imported coolies." Those responsible for the sanitary arrangements connected with the transport of coolies from the districts in which they are recruited to the tea gardens, might be able to estimate the weight which should be attached to this probability.

6. Anti-cholera inoculations were carried out on an extensive scale by Dr. Haffkine amongst tea garden coolies. Out of 28,950 of these, 7,507 were inoculated by Dr. Haffkine. The results show that amongst inoculated and non-inoculated the proportion of attacks by cholera of the former was 8 to 11·5 of the latter; and of deaths 3·73 of inoculated to 7·0 of non-inoculated. "As there is " reason to believe," writes Dr. Stephen, "that cholera is at times introduced into Assam by " tea garden coolies coming by steamer from Bengal, it seems to be desirable that arrangements " should be made for having all tea garden coolies protected by anti-cholera inoculation before they " are put on board the river steamers." In Appendix C., Dr. Hare gives an interesting account of his anti-cholera inoculations. Out of a gang of Khasi coolies who arrived at Dibrugarh on the 16th of October, he inoculated 196, leaving 159 uninoculated. Of the inoculated only four were attacked, all of whom died; of the non-inoculated 34 were attacked and 30 died. The attacks were thus, in the proportion of 2·04 per cent. of the inoculated, and 21·38 of the non-inoculated; whilst the deaths of the former were in the proportion of 2·04 per cent., and of the latter 18·86. Dr. Hare concludes: "I believe the above observations on the Khasi coolies to be unique." A feature in these figures which may strike some is the different effect which vaccination or inoculation against small-pox produces. Persons vaccinated or inoculated rarely die when attacked by small-pox; the disease when it appears in them generally does so in a mild or modified form. Not so in the case of anti-cholera inoculation; of the only four inoculated coolies who were attacked by cholera, all died.

7. *Small-pox and Vaccination.*—Although the mortality from small-pox was somewhat less than in the preceding year, it was much above the average for the five-year period, 1889–93. The ratio of small-pox deaths for the province as a whole, was in the year under report 0·77 per 1,000 of population; but this was far below the ratio for both sadr and sub-divisional towns. In sadr towns the ratio was 1·93, and in sub-divisional towns 11·00. Of the former, Dibrugarh records a ratio of 11·64 deaths, and of the latter Barpeta a ratio of no less than 36·43 deaths. The Sanitary Commissioner writes: "As noted in former reports there appears to be little relation between the " death-rates from small-pox in the several districts, and the amount of protection afforded in them " by successful vaccination." Yet, a reference to the Report on Vaccination shows that 42·97 per 1,000 of the population of the province were successfully vaccinated during the year, or greatly more than the recorded ratio of births, which latter was only 3·10. When, however, the number of children under one year of age who were vaccinated is compared with the number available for vaccination, it is at once evident that infant vaccination is the weak point in this season's, as in previous seasons', work. From Statement I it is seen that the number of children under one year of age who were successfully vaccinated in 1895–96 was 45,907; whilst the number of recorded births for 1895 was 155,631. Deducting from the latter 32,253 deaths of children under one year of age, there remained available for vaccination 123,378, and of these only 45,907 were protected against small-pox. It is thus clear that there is no lack of susceptible subjects when small-pox breaks out in the province. But although in some parts the people still obstinately refuse to have their children vaccinated, rapid progress is, on the whole, being made by the Department. The total number of persons vaccinated during the year by all agencies was 260,690, which exceeds the number for the preceding year by no fewer than 65,553; whilst the percentage of successful cases rose from 87·80 in 1894–95 to 97·74 in the year under report.

8. *Fevers* were more fatal than during the preceding year, and were credited with 92,359 deaths, equal to a ratio per 1,000 of population of 18·39, as compared with 16·95 in 1894, and with 15·75 the average for the five years 1889–93. The experiment of distributing quinine through post offices is being persevered with; but "there is not at present sufficient material to enable the Chief " Commissioner to decide definitely whether the scheme will ultimately be successful." It is added that steady progress is being made, and the Chief Commissioner proposes to sanction the extension of the system to all post offices in Assam. Deaths from *kala azar* are included in the list of deaths from fever. There were 15,894 deaths from this disease reported in 1895, as compared with 13,164 in the preceding year. Of the former number no fewer than 11,037 deaths occurred in the Nowgong district; but good reasons are given for the belief that a considerable proportion of the cases returned as *kala azar* in this district were due to ordinary malarial fever. We would like to see some explanation of the gradual decrease of this disease in some parts of the country in which it has been prevalent, and its invasion of new parts. Whether *kala azar* is due, as some assert, to the presence in the intestines of a parasite, the *anchylostomum-duodenale*, seems doubtful, seeing that this parasite has been repeatedly discovered in the intestines of persons in apparently sound health and who have not suffered from *kala azar*, whilst, on the other hand, its presence in the intestines of persons dying from *kala azar* has not been found to be constant. This question needs further investigation, and a medical officer has been appointed with a view to the systematic and continuous observation of the disease.

9. *Sanitary Works.*—As stated in the Government review of the Report, "no sanitary work " of any special importance was completed during the year, but considerable progress was made in " improving the water-supply and conservancy of the sadr and sub-divisional towns of the province." There are, however, as yet, only two towns in the province provided with a water-supply delivered

from filter-beds through pipes. The defective registration of vital statistics in these two towns makes it impossible to arrive at any certain conclusion as to the influence which the pure water-supply has had in diminishing the death-rate.

10. At one of the two meetings of the Sanitary Board held during the year, the question of village sanitation was considered. The Board came to the conclusion, wisely we think, that any legislation which might be undertaken regarding rural sanitation should be of the simplest character.

No. 8.

Memorandum by the Army Sanitary Commission on the Rajputana Sanitary Vaccination Dispensary and Jail Report for 1895.

Although, in the Ajmere district, the rainfall was some three inches above the average of the previous six years, in Merwara it was more than five inches below the average, and also considerably below it in the Native States. As the population of the Ajmere district is only 422,359, out of a total of 11,464,756 for the Ajmere-Merwara province and the Native States combined, it is evident that this deficiency of rain during the year affected all but a small portion of the country dealt with in the Report. In the south and east of Rajputana, the Agent writes, "there were no cold weather "rains, and the crops were consequently inferior; but, although the prices of grain rose in consequence, no serious scarcity was felt in the States concerned." He adds: "In the Western States "the rainfall was very scanty, and the tanks in the districts were mostly low or dry. Cattle from Jaisalmir were driven into Sind or towards Malwa in search of pasture and water." The serious consequences of drought have since then become more fully manifest; and the more remote effects on fecundity and mortality will doubtless be apparent in the vital statistics of the next and following years.

2. *Vital Statistics.*—In Ajmere-Merwara the *birth-rate* rose from a ratio of 32·23 in 1894, to a ratio of 35·29 in the year under report. This increase is credited partly to improved registration. An examination of Annual Form I will show that there is still much room for further improvement. The proportion of male to female children recorded to have been born in the province as a whole was 115·42 of the former to 100 of the latter. In two rural circles the recorded proportions are 135·20 and 136·65. In one town we find the proportion put at the extraordinary rate of 166·67 male to 100 female children. Such ratios witness to the defective state of registration. The *deaths* were fewer than during the preceding year by over 2,000; and the ratio per 1,000 of population fell from 31·02 to 26·95. As in the case of births, so with deaths, the recorded ratios are in some cases so low as to lead to the conviction that a large proportion of them failed to be registered. In two circles the ratio per 1,000 of population is a little over 18, and in another a little over 17. Whilst in the Ajmere-Merwara province vital statistics are as yet so defective, it is no wonder to find them in the Native States as a whole altogether unreliable. The recorded ratio of births for these States is only 16·75 per 1,000 of population, and of deaths only 13·66. In some of them registration is little more than a name. In two States the ratios of recorded births are only 2·18 and 7·89 respectively; whilst in two, the death ratios are only 2·20 and 4·99. Except for the purpose of indicating the backwardness of registration such statistics are obviously useless.

3. *Chief Diseases.*—In Ajmere-Merwara the deaths from *cholera* numbered 289, and in the Native States 1,049. In the preceding year Rajputana was practically free from cholera. The Administrative Medical Officer considers that the disease, in two or three outbreaks, was "clearly traceable" to the fair annually held at Pushkar:—"Almost all the persons who suffered in the city "of Ajmere had been to the same fair," whilst 12 cases occurred in the place itself. Again, it is stated that in November an outbreak occurred at Jodhpore, Nawa, Didwana, and Nagore, and that in nearly all cases it was confined to pilgrims from Pushkar. The fair is held in the month of November, a time of the year when cholera is generally in comparative abeyance. It is an important step to have traced the disease to this fair as its point of departure. If, as the Sanitary Commissioner of the North-Western Provinces and Oudh assumes, sanitary measures have proved equal to the prevention of cholera at the vastly greater gatherings of pilgrims at Hardwar in the month of April, a season of the year when the disease is more liable to become active, there should be less difficulty in preventing outbreaks at Pushkar, where the number of pilgrims is smaller and the season when the fair is held less favourable to its development and spread. At any rate, if the disease is preventible, as it is now usually held to be, Pushkar fair might afford an opportunity of demonstrating the truth of this conviction:—"Outbreaks of cholera, although every Sanitary pre-"caution is taken, constantly occur after the great November fair at Pushkar." Dr. Hendley himself thinks the facts attending the outbreaks of cholera in Rajputana in 1895 "point to the possibility of prevention." We trust he will not fail to put this question of preventibility to a convincing test.

4. *Small-pox* was credited with 754 deaths in the province of Ajmere-Merwara, or a ratio of 1·39 per 1,000 of population, as compared with an average ratio of 1·12 during the previous five years. Regarding small-pox mortality in the Native States, there are no statistics available. Of the 754

persons who died of small-pox in Ajmere-Merwara 238, or about one-third, were infants under one year of age. Annual Statement I gives the number of children under one year successfully vaccinated to have been 10,056, whilst the number born was 19,138. Of the latter, 4,167 died before reaching one year of age, leaving 14,971 available for vaccination. Deducting from this latter number those successfully vaccinated, we have a residuum of 4,915 unprotected children. Until the number of infants annually vaccinated more nearly approaches the number born and available for vaccination, susceptible material for fatal outbreaks of small-pox will not be wanting. Yet vaccination is making progress; the number of primary vaccinations rose from 13,337 in 1894 to 15,583 in the year under report; and of these latter 96·24 per cent. were successful, as compared with 98·80 in the preceding year. To some it may come as a disappointment to find a decrease in the percentage of successful cases; but in this we do not share. We take the explanation to be that stricter supervision is exercised over the work of the vaccinators. Those who have had an extensive experience of vaccination in India can hardly avoid suspecting the accuracy of returns which record such ratios of success as those which stand against the names of the majority of the Native States. A reference to Annual Statement I will show that in these a record of upwards of 99 per cent. of successful cases is quite common.

5. To a decrease in mortality from *fever* the lower ratio of total deaths during the year was chiefly due. The sale of quinine at all Post Offices in Rajputana was continued throughout the year; but "so far the experiment has not been very successful." Dr. Hendley, however, thinks it always takes time for the people to understand the advantages of a measure of this kind, and advises that the experiment should be continued for a further period.

6. The Administrative Medical Officer says that the subject of sanitation in Rajputana cities has been gone into rather more minutely than usual for several reasons, one of which is to emphasise the difficulties which surround the sanitarian. He continues:—"It is encouraging to observe that, in "spite of what appears a superhuman undertaking, something is being done, and that we may hope "that by degrees a reasonable amount of cleanliness may be achieved. It is probable that a general "change of public opinion may begin from schools, in many of which the elements of sanitation are "being taught." Without doubt, permanent advance in sanitary improvements in these States need not be looked for unless it be supported by the voluntary effort of the people themselves. From this point of view education is more likely to have good results than legislation.

7. The health of the prisoners in the Ajmere jails shows a serious falling off during the past two years. The death-rate, which in 1893 was only 11·87 per 1,000 of strength, rose to 18·01 in 1894, and more than doubled in the year under report, when it reached 45·35. It is not satisfactory to learn that, "in January an epidemic broke out in the Ajmere jail, and continued until May 1895," and that "it did not attract special attention until the Administrative Medical Officer's inspection in September." It was the opinion of this officer that the disease was a jail disease, and probably of the nature of relapsing fever. The opportunity of making an exact diagnosis of the disease during the time of its prevalence was, however, missed.

8. In the jails of the Native States the death-rate was almost the same as during the preceding years. There was a decided and satisfactory decrease in the prevalence and fatality of respiratory diseases and bowel complaints. The over-crowding commented upon in our last Memorandum still continues in the Oodeypore jail, although the death-rate fell from 39·86 in 1894 to 28·74 in the year under report. It is surely inexcusable that "there is still much scurvy in the Jhallawar jail," unless the prisoners were suffering from the disease at the time of their reception into jail. "Progress," Dr. Hendley writes, "is continually made in the Native States in the construction and management "of their central jails, and some of the district prisons and lock-ups are being improved. Special "attention is now required to the latter."

9. The report on dispensaries calls for no special notice from us.

29th May 1897.

No. 9.

Memorandum by the Army Sanitary Commission on the Medical and Sanitary Report of Coorg for 1895.

Although there was no cholera, and only seven deaths from small-pox during 1895, yet the year cannot be described as having been healthy. The number of registered deaths exceeded by 506 the number of registered births. The rainfall, although greater than that of either of the two previous years, was less than the average. There was nothing in the meteorological character of the season which would satisfactorily account for the high death-rate. The price of rice was higher than it had been during either of the preceding five years, but that of *ragi* remained about the same.

2. The low *birth-rate* and the high *death-rate* are largely explained by the facts stated in the Chief Commissioner's review of the Sanitary Report. "It must always be borne in mind that large numbers of coolies (probably not less than 50,000) annually immigrate" into Coorg with a view to employment on the coffee estates. The influence which this annual influx must exercise on the vital

statistics of Coorg may be realised from the fact that the number of immigrants exceeds more than a fourth part of the entire population. The registered number of births during the year was 4,567, and of deaths 5,073. As many of the immigrants do not bring their women with them, the birth-rate, as the Civil Surgeon observes, must always be low. On the other hand, the coolies, "recruited from the poorer classes, are often ill-fed and ill-clad," with the result that the number of deaths which occur on the ghaut roads in Coorg amongst coolies coming up or going down to the coast "is little less than a scandal." Thus, whilst from the circumstance of the coolies being mostly males, the ratio of births to population is diminished, the conditions inimical to health under which they imigrate subject them to a heavy mortality, and the death-rate is increased.

3. The most serious question dealt with in the Report is how to put a stop to this great mortality amongst the immigrating coolies; and it is one in settling which no time should be lost, alike in the interest of the coolies and those who employ them. The Commissioner writes:—"In July of the "year under report a fund was started to provide shelters on these roads. Subscriptions up to "about Rs. 3,000 were provided, but although I wrote very strongly to Government pointing out "the absolute necessity of something being done in this matter, and asking for a grant to supplement "the subscriptions, I much regret that no money has yet been passed, and without a grant the "shelters cannot be built, and the loss of life must continue." But, fortunately, the Government of India have promptly come to the rescue, and have decided it to "be imperative that the coolies should be provided with shelter as soon as possible," and without waiting for the report of the Committee sitting to investigate the question.

4. An unusual feature in the vital statistics of this small province is the preponderance of births of female as compared with births of male children. Of the former, 2,287 were registered to only 2,280 of the latter. What the normal ratio of male to female births in India generally may be is not altogether certain; but it is extremely rare to find that the recorded number of males born in any province does not largely exceed the number of females born. The number of deaths of males, on the other hand, is, in Coorg, largely in excess of the number of deaths of females. What has already been stated regarding the immigration of coolies unaccompanied by their wives would to some extent explain this anomaly; but it is more than likely that these ratios are also, in part at least, due to defective registration.

5. The only disease which was unusually fatal was *fever*. Of the 5,073 total number of deaths during the year, no fewer than 3,814 were ascribed to this cause alone. This is equal to a ratio of 23·48 per 1,000 of population. In Coorg, as elsewhere, many deaths from other diseases are doubtless credited to fever; yet, even when allowance has been made for these, the sickness and mortality from this one cause must weigh heavily on the prosperity of the province. With a view of doing something towards ameliorating the condition of the sufferers from fever, we would warmly support the proposal of the Civil Surgeon to introduce the sale of quinine by the post offices where there are no dispensaries.

6. Although, during the year, small-pox was in abeyance and was but little prevalent in the preceding year, it would be a delusion to conclude therefrom that in succeeding years the disease will continue to deal so leniently with Coorg. An examination of the returns of vaccination shows that infant vaccination is very incomplete. Against 4,567 births there were only 1,188 vaccinations of children under one year of age. Even when the 1,167 children who died under one year are deducted, there remained available for vaccination 3,400; so that only a little over one-third of these were protected against small-pox. This large proportion of unprotected children provides the elements for a fatal outbreak of small-pox when next that disease revisits Coorg in epidemic form. Only so late as 1892, the records show that no fewer than 913 deaths, equal to a ratio of 5·27 per 1,000 of population, were caused by small-pox.

7. Neither the jail nor the dispensary report calls for special remark, but we may quote from the latter the following paragraph in confirmation of the accounts already given of the sad lot of the immigrant coolies:—"The Commissioner is taking steps to have shelters built on the principal ghaut "roads for the use of coolies entering and leaving the province, and towards which the planters have "already liberally subscribed. These are greatly needed, and, I hope will tend to reduce our high "mortality, for out of the 251 deaths in the two hospitals, no less than 208 were coolies from the "plains, and only 43 were residents of Coorg, many of the former dying within a few hours of their "admission."

8. In carrying out *sanitary works*, this small province is, at least, abreast of its greater neighbours. Already the largest town, Mercara, has provided itself with a pure water-supply; and the next largest, Virajendrapet, is raising the funds needful to enable it to follow its example. The water-supply at Mercara is said to be "very much appreciated by the people, and its success has made all the other small towns clamorous for similar schemes." It is not often that one hears of sanitary improvements in India being so readily and warmly appreciated.

29th May 1897.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1895.

The year was, on the whole, a healthy one. Except that the rainfall was considerably greater than the average for the preceding ten-year period, having been 49·40 against 44·92 inches, the meteorological features of 1895 did not differ much from those ordinarily prevailing. Although the prices of the principal food-grains were somewhat below the average for the preceding two years, they were still above the average for the 10 years ending 1892.

2. *Registration* is said to have received increased attention. This may have led to local improvement in the record of *births* and *deaths;* but when we find a birth-rate of 27·0, and a death-rate of only 18·2 per 1,000 of estimated population recorded for the Presidency as the outcome of this increased attention, we must conclude, either that the conditions of life in Madras differ remarkably from those obtaining in the adjoining provinces, or that the registration of vital statistics in the former is still greatly more backward than in the latter. In the Bombay Presidency the birth-rate for the same year was 35·83, and the death-rate 28·61; in the Central Provinces 33·41 and 35·75; and in Bengal 34·57 and 31·39. The death-rate in Madras is thus so low, that the inhabitants may count on living nearly twice as long as their neighbours in Bengal and the Central Provinces. The Sanitary Commissioner uses the figures of the "estimated" population of the Presidency in making his calculations, instead of the last census figures, on which ratios are calculated in other provinces; and this circumstance somewhat, although to no great extent, affects the results. The "estimated" population numbers may, or may not, more closely approximate to the actual numbers than those obtained by adding the excess of children born over the number of deaths since 1891 to the census figures of that year. It is probable that they are nearer the truth than the last census figures themselves; but however that may be, it is inconvenient for purposes of comparison to find one province adopting one method of calculating ratios of births and deaths, and the next province another method leading to differences in the result.

3. The birth-rate estimated by actuaries for the Presidency is from 42 to 52 per 1,000 of population, and in municipalities, 33·2, the nearest approach to these rates, is reached. Judged by this result, and the fact that penalties were inflicted in 633 cases for omission to register births and deaths, it may be acknowledged that some effort is being made in municipalities to improve registration.

4. As in the record of births, so in that of deaths, municipalities give the only results which can be regarded as having any approximation to probability. For these, the ratio of deaths per 1,000 of population was 28·9, in rural towns 18·9, and in villages 19·0. In some of the rural towns, such as those of Salem and Chingleput, the ratios recorded are only 9·0 and 7·7. The ratios for the villages in some of the districts are little better; in those of Ganjam the ratio given is 12·3, and in those of Malabar 14·6. Obviously, it is a waste of time to work out elaborate calculations on data so patently worthless.

5. Of the chief diseases, *cholera* was credited with 21,172 deaths, or almost exactly half the number caused by it in the preceding year. The disease was most fatal in the two districts of South Arcot and Tinivelli; and the Sanitary Commissioner states that both "have water-supplies liable to "contamination in a very marked degree." This is no doubt true; but, as remarked by the Government in their review of the Report, "the same argument might be applied to other districts." Although it is universally acknowledged that one of the most effectual protections against cholera is the provision of a pure water-supply, experience proves that it would be unsafe to trust to this alone, if other sanitary precautions are neglected. As the Health Officer of Bombay puts it:—"To believe, "as some do believe, that, with a plentiful and pure supply of water, there will be no more an epidemic of cholera is, in my opinion, to believe in a delusion.

6. *Small-pox and Vaccination.*—The mortality from small-pox during the year was greatly less than during any of the preceding three years, and equalled a ratio per 1,000 of estimated population of only 0·1, as compared with 0·9, the average for the previous five years. Of the 5,111 deaths from this disease, 1,111 occurred amongst children under one year of age. Turning to Statement No. I in the Appendix to the Report on Vaccination for 1895–95, we find that, of the 1,007,166 cases of successful primary vaccination, only 311,230 were amongst children under one year of age. The recorded number of children born alive during 1895, exclusive of Europeans and Eurasians, as shown in Statement I, Appendix D, of the Annual Sanitary Report, was 976,572. Of these, 162·3 per 1,000 of births are stated to have died before reaching their first year of age, leaving available for vaccination upwards of 800,000 children. As only 311,230, or less than half of these, were successfully vaccinated, it is obvious that infant vaccination in Madras is still very incomplete, and that it would be a delusion to found expectations of immunity from small-pox mortality in the future on a record of a low death-rate from the disease in the year under report. The large proportion of infants annually failing to be vaccinated in this Presidency is a danger, the gravity of which will force itself into notice when small-pox next appears, as it assuredly will appear, in epidemic form. It is not a little confusing, when extracting figures from the authorized forms appended to the Vaccination Report, to find that these do not always agree with the figures in the body of the Report. For example, in paragraph 5 of the Vaccination Report, a table is given, showing the "total vaccination work done by

" all agencies throughout the Madras Presidency " in 1895–96 as 1,120,625 primary vaccinations and 77,546 re-vaccinations. Statement No. I gives, of the former, the " Grand Total " to be 1,103,099, and of the latter 75,871. No doubt these figures can be reconciled; but it would have saved trouble had the discrepancy been explained. Again, a reference to the table in page 5 of the body of the Report gives the percentage of success in primary vaccination to be 93·0, and in re-vaccination 80·3; whilst in Statement No. I the figures are 87·0 for the former and 80·5 for the latter. If the ratios from the authorized statement are accepted, they show that, as the strictness of inspection of results increases, the percentage of successful cases diminishes. It is significant that the Inspector of Vaccination himself, and District Sanitary Officers, found only 79·6 of the cases examined by them to be successful, as compared with 91·8 and 92·5 reported by the Native Deputy Inspectors and Vaccinators. Dr. Bannerman writes:—" In 1893–94 the important step was begun of undertaking " the systematic inspection of the whole range of each Deputy Inspector, with the result of revealing " an amount of corruption beyond even what was expected to exist." He believes that, in consequence of the measures being adopted, " the department will gradually be purged of idlers and " cheats, and that its statistics will in time afford some indication of the actual condition of the " population in regard to its state of protection against small-pox."

7. Dr. Bannerman confirms the opinion expressed by us in our last Memorandum, regarding the use of vaccine lymph made into a paste with glycerine. Calf-to-arm and arm-to-arm vaccination always have given, and probably always will give the best results. Although there are circumstances under which preserved lymph must necessarily be used, these are exceptional and with suitable arrangements might almost disappear. The practice of arm-to-arm vaccination, or the use of humanized lymph at all, is condemned by the Madras Government. In paragraph 8 of the Government review we find:—" It appears from paragragh 23 of the Report that humanized lymph " has, notwithstanding the remarks made in paragraph 8 of General Orders, Nos. 1,388, 1,389 L, " dated 8th August 1895, again been used," and, farther on: " The Government trusts that effective " steps will be taken by the Inspector to put a complete end to this objectionable state of things." We would like to know the grounds upon which the use of humanized vaccine lymph is so uncompromisingly condemned in Madras, and whether these grounds rest on conditions peculiar to that Presidency. In the adjoining Presidency of Bombay, as well as in other provinces of India, the use of humanized lymph is still the rule, and the use of animal lymph the exception.

8. In paragraph 107 of his Report, the Sanitary Commissioner writes:—" With the prospect of " special increase of small-pox following introduction from other Presidencies, it remains to be seen " during 1896 how far Madras has been capable of resisting the invasion." The reader might gather from this, that risk to Madras lay in the greater prevalence of small-pox in the provinces surrounding it. But, as a matter of fact, the risk is all the other way. Taking the average of the previous five years, small-pox, as estimated by the deaths it caused, was five times more prevalent in the Madras Presidency than in Bengal, six times more than in the Central Provinces, and eight times more than in Bombay. If, therefore, we adopt the practical test of immunity from small-pox as the measure of the efficiency of vaccination, it follows that the position occupied by Madras in the comparison with its neighbours, is a somewhat humiliating one.

9. *Fevers* are credited with having caused 277,337 deaths, or 6,881 more than during the preceding year. In the existing state of death registration it is not easy to say whether this increase was due to greater prevalence of fever or the result of increased attention to registration.

10. *Sanitary Works.*—The Sanitary Commissioner writes:—" Beyond the improvements effected " under major works, advance in the all-important matter of improvement of water-supply has been " less than could be wished." We gather, however, from the Annual Report of the Sanitary Engineer, that works were either in progress or were completed during the year, for the supply with water of six important towns, with populations ranging from 20,000 to 90,000 inhabitants. Besides these works, a number of other schemes for water-supply or drainage were under investigation.

11. Dr. King has hopes of being able to introduce into native households a system of sewage filtration, and believes that this would effect much good where no drains exist. He has devised an apparatus made up of a kerosine tin and a funnel which he thinks might answer the purpose of a domestic sewage filter. A modification of this, he says, allows " of forced æration by a hand bellows " and by the intermittent action of a syphon." The natives of Madras must be very much more intelligent and more appreciative of the value of sanitation than the natives of India generally get credit for, otherwise any such arrangement as that proposed would, from a combination of ignorance, apathy, and neglect, probably soon bring about an increase of the nuisance it was intended to abate. An account of Dr. King's scheme will be found in paragraphs 52 and 53 of his Report.

12. A want more pressing than that of domestic sewage filters is an adequate supply of sweepers to remove night-soil. " Indeed, in some districts, the prime difficulty as to night-soil disposal is the " obtaining of this class of labour." Dr. King thinks that the difficulty can readily be overcome by local authorities importing sweepers from more favoured localities, and guaranteeing them certain privileges as to huts and lands. This may be the case; but the occurrence of similar difficulties in other provinces would suggest that sweepers of the kind required may not be so readily induced to migrate into the Madras Presidency as Dr. King anticipates. But if scavengers cannot be got, the Sanitary Commissioner describes, in paragraph 77 of his Report, a method of conservancy which, if adopted at festivals and fairs, would render their services unnecessary. He had an opportunity of

seeing this method worked on a large scale at the Tiruvannamalai festival of 1895, and says :—"It "is certainly the most expeditious, cleanly, economical, and sanitarily sound method yet used, "and is much appreciated by natives." Yet, it is no invention of modern sanitary science, but in all essential details identical with that described in verses 12 and 13 of Chapter XXIII of Deuteronomy.

13. The Report has been greatly reduced in bulk as compared with its predecessor; and if the Sanitary Engineer's Report, which is combined in the same volume with that of the Sanitary Commissioner, is in future curtailed in accordance with the instructions of Government, a still further reduction of its bulk will follow next year.

29th May 1897.

No. 11.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1895.

Judged by its vital statistics, the year was healthier than its immediate predecessor. The registered number of births exceeded the number for 1894 by 14,036, and also the mean of the 10 preceding years by 42,665, whilst the deaths were fewer than those of 1894 by 68,639. To what degree the improved health of the Presidency was due to the climatic conditions of the season is not stated. It is true that Tables A and B give the mortuary and meteorological statistics for five selected collectorates, as well as the price of food-grains in these for the year; but what is wanted, and what has been repeatedly asked by the Commission, is a paragraph briefly recording the chief meteorological features of the year, together with some estimate of the influence which the climatic conditions are considered to have exercised on the public health. Most of the annual sanitary reports from India already deal concisely with this important question. Indeed, no sanitary report of a province can well be considered complete which omits mention of the connexion between its climate and the health of its inhabitants.

2. *Vital Statistics*—Last year the Government of Bombay observed that in nine of the districts, containing half the population of the Presidency, the registration of *births* appeared to be fairly satisfactory. In the remaining districts, and especially in those of Sind, registration was shown to be defective. The same description still holds good for the year under report. In the districts in which it has hitherto been backward, it is backward still. It might be supposed that the registration of vital statistics, forming as it does the basis of all intelligent sanitary improvement, would first attain to approximate accuracy in the city of Bombay, the centre of enlightenment of the Presidency. Recent inquiries have shown that, instead of taking the lead in accuracy of registration of births, Bombay is probably more backward in this registration matter than the most out-of-the-way village in the province. From year to year the abnormally low birth-rate of the city has been recorded, and its explanation complacently accepted, as due mainly to the relative disproportion of the sexes constituting its population. The statement that there were 170 males for every 100 females was thought to sufficiently account for the birth-rate being as low as 19·07 per 1,000 of population, as compared with 35·83 for the whole province. In the Government review the true explanation of this disparity is given :—"Only last year the vaccinators discovered 5,617 infants under one year "of age whose births had not been registered." Seeing that the total number of births registered for that year was only 14,796, we have a recorded birth-rate per 1,000 of population of 18·3 instead of 25·3, and even this last may be short of the reality. This discovery has helped to explain another striking feature of the vital statistics of Bombay city. The high proportion of still-born to live-born children has annually been the subject of comment. If, as is probable, still-births are treated as deaths, and therefore like them recorded with comparative accuracy, it follows that the ratio of these should have been calculated on 20,413 and not on 14,796 live births. Registration being so defective in Bombay city, it need cause no surprise to find in a Sind district such records as a birth-rate of 19·3, or a ratio of 131·8 male children born to every 100 female children. The Sanitary Commissioner writes :—"The registration of births in Sind is apparently defective throughout the "province, and especially in the Collectorate of Hyderabad."

3. The registration of *deaths* is undoubtedly less defective than the registration of births, a result due, as remarked in the Government review, "to the necessity for burial." The ratio of deaths per 1,900 of population fell from 32·26 in 1894 to 28·61 in the year under notice, and was almost the same as the decennial mean. The ratio of 109 deaths of males to every 100 deaths of females appears to lend support to belief in the accuracy of the birth registration, according to which 108 males were born for every 100 females. But it is probable that in the record of deaths of females, as in the record of their births, omissions are more frequent than in the record of men's deaths.

4. The discrepancy between the ratios given of deaths amongst Mahommedans as compared with the ratios amongst Hindus, has attracted the attention of the Government. For the Presidency as a whole, the ratios are 20·5 of the former to 30·8 of the latter. The disproportion is most striking in Sind, and may be credited, as in the case of the other abnormal features of the record of vital

statistics throughout the country, to imperfect registration. The backward condition of registration in that division of the Presidency need excite no wonder when we find it stated that—"In many of "the larger towns and villages of the rural circles the proper census population figures are not even "recorded."

5. *Cholera* was in abeyance during the year. Only 8,890 deaths were recorded as due to it, as compared with 33,588 in 1894. It is noticeable that the year began well; there were only 37 deaths from cholera in January, and 19 in February. The severe epidemic of 1894 had almost died out; in the last month of that year there were only 92 deaths. During the year under report, cholera continued slowly to increase as the hot weather advanced, until it reached its maximum prevalence in August, in which month it caused 1,652 deaths. After this, it did not decrease rapidly as in the preceding year, but even in December was credited with 608 deaths, making it probable that 1896 would not fare so well in its first months as 1895. There was nothing in the behaviour of the disease in the places attacked by it specially deserving of record. As observed by the Government of India—"Some portions of the Report might have been condensed, and in "especial the section on Cholera, which is largely made up of quotations from the reports of the "Deputy Sanitary Commissioners." Some of these quotations are without doubt of interest, and especially the remarks by the Deputy Sanitary Commissioner, Southern Registration District, quoted at page 27; but the greater part of them might have been omitted without impairing the usefulness of the Report. The evidence given to prove importation of cholera into places attacked is of the usual description, too often inexact, and generally inconclusive.

6. *Small-pox and Vaccination.*—As from each of the other chief diseases, so from small-pox there was a diminished mortality during the year, both as compared with that for the preceding year and the mean of the previous ten-year period. Only twice during the past 12 years have there been so few deaths from this disease. As usual, a disproportionate share of the mortality fell on children under one year of age. Over a fourth of the total number of deaths occurred in this group. Amongst children of ages between 1 and 12 there were 1,255 deaths, leaving only 431 to be accounted for amongst persons of all ages above 12 years.

7. Turning to the separate Report on Vaccination, we find that 732,648 children were primarily vaccinated during the vaccination season 1895-96, and that of these 683,044, or 93·23 per cent., were successfully vaccinated. Of re-vaccinations there were 78,156, with a percentage of successful cases of 57·88. In our memorandum on the statistics of vaccination for Madras city for this same year, we expressed some surprise at the high percentage of successful cases obtained there. In primary vaccinations there were 99·66 per cent. of the cases successful, and 89·76 in re-vaccination, as compared with 93·2 in the case of the former, and 57·8 in the case of the latter in the Bombay Presidency. Of the children under one year of age calculated to have been available for vaccination, 79·88 per cent. were successfully vaccinated, leaving an unprotected residuum of over 20 per cent. Amongst this latter group the ratio of small-pox deaths is invariably high, and in proportion as vaccination reaches and reduces it, so will small-pox mortality be correspondingly diminished. Under even the most rigorous system of infant vaccination a certain number will still be left unprotected, there will always be some children whose state of health from various ailments renders them unfit for vaccination.

8. The work of the Department for the year cannot be regarded as other than satisfactory. The primary vaccinations exceeded those of the preceding year by 20,292, and the re-vaccinations by 16,986. On the other hand, their was a slight decrease in the percentage of successful cases amongst both primary vaccinations and re-vaccinations as compared with 1894. Owing partly to the difficulty of getting parents to allow vaccine lymph to be taken from the vesicles on the arms of their children, it has been found expedient to practise animal vaccination as supplementary to vaccination with human lymph. The returns show, however, that by far the greater number of operations are still performed with the latter. In our memorandum for 1894, we commented on the high cost of each successful case of vaccination in this Presidency as compared with the cost in other provinces. This, instead of diminishing, increases. In 1894 it was six annas and two pies; in the year under report it was six annas and three pies per successful case.

9. We agree with the opinion expressed in paragraph five of the Government review of the Report on Vaccination, that this might "be made shorter and perhaps more valuable by omitting from the "text mere repetitions of figures which already appear clearly in the statistical tables incorporated "in the various paragraphs, and by substituting, where necessary, such comments as would elucidate "or explain the facts implied."

10. *Fever*, although less fatal than during the preceding year, yet caused by far the greater part of the total mortality of the year. Of the 538,540 deaths from all causes, 388,848 are ascribed to fever. Although this number is less by 40,246 than the number for 1894, it is largely above the mean for the previous ten years, and was only exceeded in two of those years. The prevalence of fever is considered by the Deputy Sanitary Commissioner, Western Registration District, to have been increased, not by an unusually heavy rainfall for the year—for as a matter of fact, the rainfall was less than in 1894—but by heavy rain late in the season. His opinion, that the period at which the rainfall has possibly more to do with the general health than the actual amount of rainfall, seems reasonable:—"When late rain falls, as it did last year, the people are much more liable to "chills than when a period of comparative warmth comes between the rains and the cold season. "November and December last year showed an unusual high mortality." This opinion is shared by the Deputy Sanitary Commissioner of the Central Registration District. The influence of the price of food on fever mortality could not be determined. Regarding the Poona Collectorate we

read:—"The striking fact is the cheapness of all cereals as compared with former years; the "number of deaths from fever is, however, the largest since 1890, except last year."

11. *Sanitary Works.*—In the 168 municipalities, excluding the city of Bombay, upwards of 18 lakhs of rupees were spent on sanitary works. Of this amount, nearly half was expended in carrying out the ordinary conservancy of the towns. Close on five lakhs were spent on improving the water-supply. No large sanitary work seems to have been undertaken during the year. The extent of the sanitary work executed by District Boards may be estimated from the amount of money spent. This was a little over five lakhs of rupees. Spread over a country with upwards of fifteen millions of inhabitants, such a sum could go but a little way towards ameliorating the insanitary surroundings of so great a population.

12. Fourteen pages are given to the Report of the Sanitary Board for 1896. The Government of India consider that "too much detail regarding unimportant matters has been reproduced" from this Report. No one who has read through these fourteen pages is likely to differ from such an opinion.

13. The Annual Report of the Health Officer of the port of Bombay, which forms Appendix II of the Sanitary Commissioner's Report, is of much interest, especially at the present time. The advocates of rigorous quarantine, as the most effectual means of preventing the spread of communicable diseases, might read Dr. Crimmin's account of its results given in pages 26 and 27 of his Report. Here the following extract must suffice:—"The 'Husseinee' left Bombay on the "10th April, and arrived at Cameron on 18th idem. During the voyage she had no deaths, and "no pilgrims required medical treatment. On 24th April, *i.e.*, on the 6th day of quarantine, and "on the 14th day from departure from Bombay, cholera broke out amongst her pilgrims in camp, "and lasted with fresh imposition of quarantine until 26th May. Finally, on 31st May, as it was "clear that the 15 days' quarantine imposed after each case would, if reckoned from the 25th, "prevent the pilgrims from reaching Jeddah in time for the Haj, the vessel re-embarked the "passengers and returned to Bombay without the pilgrims having been able to perform their Haj. "They had been for 43 days in quarantine at Camaran, and 22 of them had perished—15 from "cholera and seven from ordinary diseases—all victims to an insanitary quarantine station." It is added that the "Husseinee" is one of the best of the pilgrim liners, and that her sanitary condition prior to the embarkation of the passengers at Bombay was excellent.

14. The health of the port of Bombay is said to have markedly improved during the year:—"The "retarding elements in the sanitary improvement of the port and foreshore are private owners and "the Municipal Corporation."

29th May 1897.

No. 12.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Hyderabad Assigned Districts for 1895.

Only twice during the last 28 years has the death-rate of 1895 been exceeded. The year was unhealthy beyond the average; yet there was nothing exceptional either in the meteorological conditions which prevailed, or in the price of the food supplies, which would satisfactorily account for this. The rainfall was abnormally light, and the mean temperature during the hot weather was abnormally high. The former of these conditions has generally been adduced to account for the healthiness of a season, or at all events its opposite, excessive rainfall, to account for its unhealthiness. Undoubtedly, abnormally high temperature is acknowledged to be injurious to health; but an examination of the table given on page 11 of Dr. Little's Report does not reveal any very striking difference between the temperature of 1895 and the mean of the previous five years at the three stations where observations were taken. As regards food, it is stated that *jowari*, the staple food grain of the province, was cheaper than the average of the previous five years.

2. *Vital Statistics.*—Taken as a whole, the registration of births and deaths is probably as accurately carried out in Berar as in other Indian provinces, if we take as the ground of this conclusion the approximation of the ratios to the standard fixed by actuaries for India. The inspection of birth and death registers is earnestly insisted on by the Commissioner, the Resident, and the Government of India; and without any doubt, if such inspection is thorough, it will exercise an effectual check on neglect, or worse, in the keeping of these registers. But to ensure thoroughness, more time is needful than those who have not themselves had experience of such work might suppose. Nothing short of a comparison of the registers with the result of a house-to-house inquiry can be regarded as an efficient inspection; and to carry this out, patience, time, and labour are required; more time than hard-worked district officers can often have at their disposal. It is only needful to glance at the results obtained by inspecting officers in Table No. 1, page 2 of the Report, to be convinced that there must have been differences in the strictness of the tests applied by them. Assistant and Extra Assistant Commissioners, and Civil Surgeons, found respectively only 1·5 and 1·2 per cent. of the registers defective; whilst Deputy Commissioners found 13·5, and District Superintendents of Police 9·6 per cent. defective. So wide a divergence in results can hardly be

attributed entirely to difference in the accuracy of the registers, and is likely to have been due, in part at least, to the mode in which the inspection was carried out. It is disappointing to find that so few registers were inspected by Civil Surgeons; and, looking at the small percentage of defects discovered at these inspections, there seems room to doubt if the examinations, few although they were, could have been of a very thorough description. Regret is expressed by the reviewing officers that there should have been a considerable falling-off in the number of registers examined in 1895, compared with the number examined during the preceding year. It is important that as many as possible of these registers should be annually inspected; but it is above all important that when inspection is made it should be thorough.

3. It would naturally be expected that the subject of the registration of births and deaths would receive more attention in municipalities than in rural circles. Such, however, does not appear to be the case. The Commissioner writes:—"The Municipal Committees have failed to show sufficient "interest in the matter of vital statistics, and no penalties were imposed for breach of the rules, "though the attention of all municipal committees was specially directed to this subject in accordance "with orders passed last year."

4. *Births.*—The birth-rate for 1895 rose to 37·2 per 1,000 of population, and exceeded that of the preceeding year by 3·9. In four of the six districts of the province the rate exceeded 40 per 1,000 of population; in the remaining two it was only 25·4 and 27·3 respectively. Although registration is the most backward in these two latter districts, Wun and Basim, Dr. Little thinks other causes have contributed to the lowness of their birth-rates. He personally examined the registers in several villages of Basim and Wun districts, and was struck by the high death and low birth rates recorded. Yet, he found in most instances the registers to be pretty accurately kept. In the Wun district complaint was made of scarcity of food in 1894 and 1895, on account of bad crops and the pressure of the Forest laws. This had led to the population of many villages being reduced. There were, thus, exceptional circumstances, in the case of the Wun district at least, to account for the low birth-rate, apart from the backward state of registration.

5. There were 105·2 births of males recorded for every 100 births of females. This may be regarded as a fair average, and tends to support the belief that the registration of births is, as a whole, fairly accurate. At the same time, an examination of the returns shows that there are startling variations in the proportion of the sexes of the children born in different circles. In one circle, the proportion of male to female births recorded is as high as 154·5 to 100, and in another as low as 82·2 to 100. Inquiry would probably show such extreme ratios to be due to defective registration.

6. *Deaths.*—The recorded number of deaths exceeded the recorded number of births by no less than 35,985, and was equal to a ratio of 49·9 per 1,000 of population. The ratio varied from 58·4 in Basim to 41·6 in the Wun district. In the former of these two districts the recorded birth-rate was only 27·3 per 1,000 of population; so that the death-rate more than doubled the birth-rate. In one rural circle of this district, with a population of nearly 40,000, the death-rate was 7·31 per 1,000. The high death-rate of the province was chiefly the consequence of excessive prevalence of fevers, cholera, and bowel complaints. The deaths recorded under the head of "Other causes" were also greatly more than those recorded in the preceding year, and than the average for the previous 10 years. From small-pox alone of the chief diseases there was no increase of mortality for the year.

7. *Chief Diseases.*—Fevers, although destroying life in a less sudden and sensational way than cholera, and having less than two pages of the report devoted to its history, as compared with eight pages and a coloured map to cholera, caused six deaths for every one caused by the latter. To this disease alone, a death-rate of 23·2 per 1,000 was due, and yet, when we look for some explanation of its excessive prevalence, we find that the commonly assigned cause, a heavy monsoon, not only did not occur during 1895, but that, on the contrary, the rainfall was exceptionally light. Dr. Little says:—"Until we know more regarding the origin of malaria, it is useless speculating as to the "causes which operate to favour the prevalence in certain localities more than others of the class of "disease ranged under the head Fevers." In Wun, the mortality from fever was higher than in any of the other five districts. In this district it was 27·7 per 1,000 of population. The condition of the inhabitants of Wun district as described by the Sanitary Commissioner is a miserable one:—"These "people are very poor, scantily clad, and live from hand to mouth. They usually work as field "labourers, and in seasons of scanty harvest almost starve, sustaining life with jungle fruits, especially "the *mowha* blossom and the seeds of grasses." Endeavours have been made to alleviate their sufferings from fever by the sale to them of cheap quinine; but the aboriginal Gond and Kulam inhabitants are too poor and too ignorant to avail themselves of the remedy. Such people living under such conditions will continue to fall easy victims to disease in spite of every effort which the most benevolent Government can make to save them.

8. *Cholera.*—The history of this disease in the year under notice is a continuation of its history from the previous year. In December 1894 the deaths from cholera numbered 158, and throughout the year under report no month nor district was free from it. The total number of deaths recorded as due to cholera was 11,919, or 4·2 per 1,000 of population. But such a record in Berar is by no means exceptional. During the 28 years for which statistics exist, this rate was reached or exceeded on the average every fourth year. Dr. Little considers cholera to be endemic in the province. Yet, in two consecutive years the return given on page 12 shows that there were no deaths in the province from it during the one, and only two during the other.

9. Extracts from the reports of Civil Surgeons are given, detailing the circumstances under which the disease made its appearance in their districts. In some cases evidence has been adduced to prove that it was imported into the places attacked. The Civil Surgeon of Buldana clearly traced the first case of cholera, which occurred on the 16th of May at the village of Belodi, to importation. On the 13th of May, a man named Mimah visited the village of Manegaon, where cholera was said to be prevalent, and returned to Belodi on the 15th. The first case of cholera occurred in Belodi the day after Mimah's return. Therefore, the disease was, in the Civil Surgeon's opinion, imported. Unfortunately for the soundness of this conclusion, it was subsequently ascertained that no case of cholera occurred in the Jalagaon circle, in which the village of Manegaon is situated, until the 21st of May, or six days after the return of the man Mimah to Belodi. The Civil Surgeon of Akola attributes the appearance of the disease, in one instance, to local causes. The Sanitary Commissioner himself, believing cholera to be endemic in Berar, would not, of course, consider importation necessary to explain an outbreak.

10. The Resident of Hyderabad in his review of the Report thinks that "whether cholera is "endemic in Berar or is imported, there is no better prophylactic against it than pure water." He further adds:—"It is not meant, of course, that conservancy or drainage should be neglected; if "they are, the good effects of a pure water supply are likely to be neutralized." In the present state of our knowledge of the disease, the measures most likely to be successful in preventing it could not be better indicated.

11. *Small-pox* was credited with only 556 deaths during the year, or a ratio of ·2 per 1,000 of population. Of the total deaths from this disease, 205, or 36·9 per cent. occurred amongst infants under one year of age, and 312, or 56·1 per cent., amongst children over one and under 12 years of age. "Thus," as the Sanitary Commissioner writes, "out of 100 deaths amongst persons of all ages, "93 were reported to have occurred under the age of 12, which demonstrates the importance of "infantile vaccination." Table No. 13, given at page 209 of the Report, is a satisfactory record of the steady diminution of small-pox mortality accompanying corresponding progress in the spread of vaccination since the introduction of the latter into Berar in 1868. An examination of Table No. 13 of the Report on Vaccination for the year, shows that the Province of Berar occupies a very favourable position as regards vaccination, when compared with other provinces. Judged by the practical test of the diminution of deaths from small-pox, the only provinces showing better results are Assam and Bombay. Dr. Little is justified in saying:—"The success secured in the reduction of the "death-rate from small-pox is one of the most gratifying results obtained by the Sanitary "Department." This success the Resident acknowledges to be due in great part to the strong personal interest Dr. Little takes in vaccination, and to the supervision he has exercised over the Department.

12. *Dysentery and Diarrhœa* accounted for 24,452 deaths, a number not reached in any year since 1878. These diseases increased and diminished in their prevalence throughout the year with the increase and diminution of fever, and were doubtless largely influenced by the same causes as the latter.

13. *Sanitary Works.*—The 11 municipalities expended during the year somewhat over a lakh of rupees on drainage, water-supply, and domestic cleansing. From this it is evident that no large scheme of sanitary improvement under the headings mentioned was undertaken. Dr. Little states that "conservancy and general measures receive considerable attention, but a little more individual "attention by members of Committee in their respective wards is desirable." When it is seen that the estimated annual income of the whole of the municipalities amounts to a total of less than two and a half lakhs of rupees, it cannot be expected that sanitary improvement in Berar should be very rapid. At the same time, the Report shows that the limited funds at their disposal are being turned to good account by the authorities.

14. In the year 1888 a systematic sanitary survey of the towns and villages of Berar was commenced, and up to 1895 the total number of surveys completed of the former was 33, and of the latter 626, leaving 6 towns and 5,160 villages still to be surveyed. At the rate it has been proceeding since 1888, the survey of villages will not be completed for nearly 60 years. Writing of urban and rural sanitation in the Buldana district, Dr. Little says:—"There is not much progress to be reported "in this direction. The people for the most part neither care for nor want sanitation, and until "legislation is brought to bear, I fear we cannot do much to effect reform." Perhaps *education* in this sentence might be substituted for *legislation.*

29th May 1897.

No. 13.

Memorandum by the Army Sanitary Commission on the Administrative Report of the Commissioners of the Town of Calcutta for 1895–96.

As usual, the Report deals with the health of Calcutta for the calendar year only. In our memorandum for 1894 we stated that the health of the town for that year was not good. During the year under notice it has been greatly worse. The birth-rate, which in 1894 had fallen to 16·8 per

1,000 of population, still further fell in 1895 to 16·0; whilst the death-rate, which had in the former year risen to 32·9, rose to 39·6. This, as the Health Officer remarks, "is a very unsatisfactory condition of matters."

2. It does not appear that there was in the meteorological character of the season any deviation from normal sufficient to account for this great increase in the death-rate. Neither could the increase be accounted for by the dearness of food. On page 135 a table is given which shows the comparative price of "common" rice for each of the last 11 years. From this it is seen that rice was cheaper in 1895 than during either of the preceding three years. Although both cholera and small-pox were more fatal during 1895 than during the previous year, the chief increase in the death-rate was due to fever. From this last the number of deaths rose from 8,963 in 1894 to 11,345 in the year under notice, and constituted 41·9 per cent. of the total mortality of Calcutta. This increased mortality from fever was not confined to any one part of the town and suburbs, although it was specially marked in the canal area, which is low-lying, water-logged and sewer-logged to a greater extent than any other part of the town. "The high rate of mortality from fever in the "suburbs," writes Dr. Simpson, "is due to its undrained condition aggravated by the introduction "of a public water-supply, without adequate provision for the removal of the waste water." With regards to the town, he adds, "There is provision for the removal of waste water, but the defects in "the drainage system in relation to the outfall place it in the rainy season in much the same position "as the suburbs, and the system possesses its own peculiarities in construction that render it a "manufactory of fever under favourable climatic conditions." No one will question that the local conditions described must be potent factors in the production of fever; but they are permanent causes, and although their influence may show no tendency to diminish from year to year, they seem inadequate to account for the sudden increase in the mortality from fever during 1895. If, however, we look beyond Calcutta, we find that this increase in the death-rate from fever, aggravated although it doubtless must have been in the case of Calcutta itself by the local insanitary conditions described by the Health Officer, was due to general influences which affected the surrounding country as well as the town. Turning to page 31 of the Report of the Sanitary Commissioner of Bengal for 1895, we find that in the districts of 24-Parganas, Howrah and Hooghly the death-rate from fever rose, in the first from 17·25 to 21·05, in the second from 13·09 to 16·20; and in the last from 25·46 to 28·48. In Calcutta it simultaneously rose from 13·15 to 16·64. In other words, Calcutta shared in nearly the same proportion as the surrounding country this increase of fever mortality during the year 1895. The importance of separating the local from general causes of sickness we took occasion to notice in our memorandum on the Administration Report of the Commissioners of Bombay for the same year.

3. Cholera, as well as fever, was greatly more prevalent than during the preceding year. The number of deaths from this disease rose from 869 in 1893 and 1,695 in 1894 to 2,090 in the year under report. The Health Officer says:—"The part which the tanks of Calcutta play in cholera "prevalence is well known." But seeing that these are becoming annually fewer in number, the increase in cholera prevalence can hardly be credited to the tanks. Another factor concerned in the causation of cholera is stated to have been the occurrence of cholera microbes in the river at and near the bathing ghâts, and the supply of this water to the bathing platforms in the towns. We are not told precisely how this acted in the production of cholera, or if the microbes were discovered more frequently or in greater abundance during the past than in previous years. In addition, the passage of pilgrims through Calcutta is considered to be concerned in the causation of cholera. "The pilgrims are only for a short time in the town, but they remain sufficiently long to leave "behind them many new centres of cholera infection." No return appears to be given showing the number of pilgrims who suffered from cholera whilst passing through Calcutta; so that we have no data from which to estimate the part which these played in the causation of cholera in 1895. It may be presumed, however, that their visit to the town is of annual occurrence, and that cholera prevalence in other years, no less than in 1895, was influenced by their passage.

As a prophylactic against cholera, 2,038 persons were inoculated by Professor Haffkine's method during the year. Dr. Simpson says:—"Precise observations have proved that this method reduces "the mortality in the first four days by an average of 3·24 times, and that the people inoculated "after this period acquire a protection which, for a year at least, renders them 22·62 times safer "than the uninoculated." Yet the people of Calcutta do not appear to be quite satisfied with the degree of protection thus conferred, otherwise more than 2,038 would surely have had themselves protected against a deadly disease which was never absent from their midst throughout the year.

It is satisfactory to find on record that "the filtered water has maintained its general character as "a pure and wholesome water throughout the year." Those who insist that cholera is "solely a water-borne" disease will find it somewhat difficult to get their theory to fit in easily with the facts stated, or with the figures recorded on page 169 of the Report. According to these latter, of 2,147 cases found on inquiry to be genuine cases of cholera, 457 were traced to importation from places outside Calcutta, 122 to communication with previous cases, and 337 were associated with unwholesome food, 125 with defective water supply, 32 with milk brought from outside town and suspected to be diluted with polluted water, and 275 with overcrowding and other insanitary conditions. The connection traced between the disease and the conditions associated with its appearance is thus seen to be of anything but a constant nature, and avowedly to rest in some cases on suspicion rather than on ascertained facts.

4. To the increased mortality of the year small-pox largely contributed. The number of deaths from this disease rose from 31 in 1893 to 405 in 1894; and to no fewer than 2,220 in the year

under report. Of this last number, it is disappointing to find that 501, or nearly one-fourth, occurred amongst those who had previously been vaccinated. But of these vaccinated cases the greater number of deaths took place amongst persons of ages between 10 and 40 years, "plainly showing," as Dr. Simpson observes, "the necessity of re-vaccination." As usual, the brunt of the epidemic fell on children under five years of age who had not been protected by vaccination, inoculation, or a previous attack of small-pox. Amongst this group 708 deaths occurred, or nearly a third of the total number. The contrast between the fate of these unprotected children and those who had undergone vaccination places the prophylactic value of vaccination in the strongest light. There was not a single death amongst vaccinated children under five years of age. Even amongst vaccinated persons of ages up to 20 years, although there were 34 attacks, no death resulted. Equally strong is the proof in favour of the protection conferred by re-vaccination. During this severe epidemic not a single case of small-pox occurred amongst persons "who had been or were re-vaccinated."

The Health Officer describes some of the difficulties which are met with in dealing with an outbreak of small-pox in Calcutta. The chief of these are the concealment of those attacked by the disease, through dread of their being removed to hospital, and to its being difficult or impracticable to secure the isolation of small-pox patients. "The law gives no power to the sanitary authorities to isolate "females and infants by removal to hospital;" and infants under five years of age were the greatest sufferers from small-pox.

5. Turning to the returns of vaccination, the first point that strikes us is the obvious neglect of infant vaccination. The number of children born was 10,945. Deducting from these, 4,663 who died under one year of age, 6,282 remained available for vaccination. But the number of children under one year of age vaccinated was only 5,253, leaving 1,029 unprotected. No doubt the total number of persons who underwent primary vaccination, 15,184, is largely in excess of the number of children born; but, nevertheless, a severe epidemic of small pox occurred. This shows that in protecting a community against small-pox it is of the first importance to secure thorough infant vaccination. During the prevalence of the epidemic there were no fewer than 39,789 re-vaccinations performed. Of this large number only 4,080 proved successful. The ratio of ascertained successful cases of re-vaccination was thus 13·32. In Madras city the percentage of success in re-vaccinations is recorded as having been 89·76. It may be that, there, any appearance of local irritation following the operation was taken as indicating success. Besides the difficulties already described as having been met with in the endeavour to extinguish this severe epidemic of small-pox, scarcity of vaccine lymph is also mentioned. "During the hot months, such as May and June, calf lymph deteriorated, and all "vaccinations proved unsuccessful." But were infant vaccination thoroughly enforced, outbreaks of small-pox on the scale of that of 1896 would probably rarely occur, and the difficulties complained of would not have to be faced.

6. As in the case of the diseases already briefly dealt with, diarrhœa and dysentery were more prevalent than during the preceding year. To these, 3,269 deaths were attributed, as compared with 3,136 in 1894, and with a mean of 2,769 for the six years 1889–94. In short, the year was an unhealthy one, and the high rate of mortality due, not to the epidemic prevalence of one disease, but the result of a general increase in the severity of nearly all diseases.

7. *Sanitary Works.*—Sanitary authorities maintain that there is no better index of the sanitary state of a town than the record of its infant mortality. Measured by this scale, Calcutta is one of the most backward cities, as regards its sanitary condition, in the world. Of the children born, 476·0, or nearly half, died before reaching one year of age. Little wonder if Dr. Simpson writes:—
"The high mortality amongst infants is a prominent and discreditable feature of Calcutta, and "urgently calls for improved sanitation in connection with the construction and cleanliness of "dwellings, and the proper regulation of the milk supply, in addition to the general drainage and "cleanliness of the town."

For five years the general drainage question has been discussed, and at length a definite conclusion regarding it would seem to have been arrived at. If the efficiency of the scheme proposed should prove to be commensurate with its cost, it ought to be a great success. It is estimated to cost about 79 lakhs of rupees, and this is less than half the estimate for the alternative scheme submitted to the Commissioners. Although the efficient drainage of Calcutta is one of its most urgent sanitary needs, scarcely, if at all, less important is the pressing necessity of proper building laws. "It is impossible," writes the Health Officer, "for a city to grow up in a healthy state in a haphazard manner, such as is "permitted in Calcutta, where areas have sprung up, and are springing up, all over the town in "defiance of every canon of sanitary law." As the Lieutenant-Governor remarks in his review of the Health Officer's Report, these observations deserve, more especially at the present time, the most serious consideration on the part of the Commissioners. It is well known that the plague, now knocking at the doors of many Indian towns, finds its most congenial habitat in crowded and insanitary dwellings, such as those which, for years, have been allowed to grow up in Calcutta in spite of the earnest warnings and remonstrances of the Health Officer.

29th May 1897.

No. 14.

Memorandum by the Army Sanitary Commission on the Administration Report of the Madras Municipality for 1895–96.

This Report has the merit of brevity. The main facts relating to the public health of the City of Madras are set forth clearly and concisely. The year, judged from the statistics of mortality, was not quite so healthy as its predecessor. But it is explained by the writer of the Report that the higher death-rate was in part due to the increase in the birth-rate. The prevailing meteorological conditions do not show any striking deviation from normal. An opinion is expressed that the increase in the number of bowel complaints in August, September, and October may partly be attributed to the damp and cloudy weather experienced during those months. But it is generally believed that high temperature during the autumn months in India, as in England, favours the prevalence of those complaints; and it is stated that the mean temperature of the air was below normal in August and October. There was no appreciable change in the price of food as compared with that of the previous year, except in the case of *Ragi*, which was much cheaper.

Vital Statistics.—The *births* exceeded in number those of 1894 by 2,075. This increase took place in the second half of the year, and is said to have been due to food having become appreciably cheaper during the year 1894, and to its remaining so during the year under report. The birth-rate per 1,000 of population was 42·2, and was the highest recorded during the past 10 years. The number of still-births was 513 as compared with 541 in the preceding year. These figures contrast strikingly with the corresponding figures for the City of Bombay. In this latter the birth-rate was less than half that recorded in Madras, or 19·08 as compared with 42·2; whilst of a total number of 17,154 children born in Bombay, 1,470 were still-born, as compared with 513, out of a total in Madras of 19,650. It would be of interest to have an explanation of this remarkable difference between the two cities, with regard to the number of still-born children.

The *deaths* registered during the year numbered 17,052, against 16,542 in 1894, and were in the proportion of 37·6 per 1,000 of population, the mean for the decade being 38·7. Registration of births and deaths would appear to be carried out with much thoroughness; only one birth and two deaths remain unregistered. Even as regards these three cases, a satisfactory explanation is given in each of the reason which led to its having escaped registration.

Chief Diseases.—As usual, fevers caused a greater number of deaths than any other single disease. Under this head 6,265 deaths are entered, or equal to 13·8 per 1,000 of the population. This is slightly in excess of the mortality from fevers in 1894, and considerably in excess of the average for the previous 10 years. The permanent causes of the prevalence of fever are well known, and until they are removed it is hopeless to look for a diminution of this prevalence. The chief of these causes are defective drainage, and an impure water supply. Both exist in Madras, and as yet no substantial progress has been made towards their removal. Of the temporary causes, the President assigns importance to the price of food; the prevalence of fever has been found to increase and diminish with the rise and fall of the price of food.

Bowel complaints were considerably less fatal than during 1894, and greatly less fatal than they were on the average during the previous 10 years.

Small-pox and Vaccination.—The disease and its antidote, may be taken together. The former is credited with only three deaths, the smallest number recorded from this disease in any year except 1886, when only one death occurred. No better proof could be given of the efficiency with which vaccination is carried out. It is worthy of note, also, that all three deaths were of persons over 20 years of age, showing that infant vaccination, neglect of which is so generally the main cause of small-pox mortality, receives careful attention in Madras. This immunity of young children from small-pox is sufficiently accounted for by the vaccination returns. From these latter it is seen that, of 19,137 children born, 519 were still-born and 5,408 died under one year of age. This leaves available for vaccination 13,496. Referring to the table given in Appendix IV, it is found that 13,027 of these were successfully vaccinated. Of the remainder, 33 were unsuccessfully vaccinated, whilst the result was not ascertained in 127 cases. Only 309 remain to be accounted for; and many of these, out of so large a total as 13,496 children, would doubtless be found unfit to undergo vaccination, owing to infantile ailments of various kinds.

The total number of vaccinations performed during the year was 27,024. Of these, however, only 18,877 were primary vaccinations. The remainder, 8,147, were cases of re-vaccination. In both primary and re-vaccination operations, the recorded percentage of successful cases is somewhat surprising. Of the former, 99·66 per cent. are returned as having been successful, and of the latter, 89·76. If almost cent. per cent. of the primary operations were genuinely successful, we cannot accept without hesitation a return which gives so high a percentage of re-vaccinations. In our memorandum of last year we commented on the high percentage of successful cases of re-vaccination recorded in Madras, and pointed out that in other provinces of India, such as Bombay and the North-Western provinces, nothing approaching to these results had been attained. It should not be forgotten that, if the quality of primary vaccination is high, the percentage of successful re-vaccinations following thereupon will be proportionately low. Or, put in another way, a high percentage of successful re-vaccination does not indicate a high quality of the primary vaccination which preceded it. But the practical test of the efficiency of vaccination is, after all, the immunity from small-pox which it confers, and, judged by this test, vaccination as performed in Madras city is efficient.

Cholera caused 122 deaths, as compared with 77 during the previous year. Yet the number was far below the average of the preceding 10 years, which was 481·8. One hardly expects to read that part of the increase in the number of deaths over the number in the last quarter of 1894 "was owing to the outbreak of cholera in the Government Lunatic Asylum." One would naturally expect to find an institution under the direct management of a medical officer, and presumably fortified by scientific sanitary precautions against the ingress of epidemic disease, to be less likely to be attacked by cholera than insanitary city slums; and yet, as in the case of the Jamsetjee Hospital in Bombay in 1894, so in the Madras Lunatic Asylum in 1895, cholera passes over the crowded slums and elects as its field of operation institutions arranged and managed in conformity with modern sanitary principles.

Sanitary Defects.—Practically, no progress has been made during the year in providing the city with an efficient drainage system. The expenditure of the year under the head of drainage amounted to Rs. 52,333. Seeing that the scheme which the Commissioners favour is estimated to cost about 28 lakhs, it is evident that this still remains in abeyance. Yet, the President writes:—"No great "reduction in the mortality of the town can be expected until a good system of drainage and sewerage "has been carried out." It is encouraging, however, to learn that Government have made a grant of three-and-a-half lakhs of rupees towards the drainage of Madras, "and it is hoped that some progress may be made during the next year."

Although the water supply has been considerably improved as regards its quantity, no steps have yet been taken to improve its quality. "The analysis of water," writes the President, "is anything but satisfactory." Considering that the supply is unfiltered, this is not much to be wondered at; but, as stated last year, the cost of any efficient scheme hitherto proposed for filtering the water supply of Madras would be beyond the means of the Municipality.

The difficulty in obtaining a sufficiency of conservancy coolies to carry on the every day details of cleansing the city has become serious. "It has been found absolutely impossible to obtain the full complement of scavengers for the conservancy work in Madras." One of the reasons given for the decrease in the quantity of rubbish carted away as compared with that carted during the previous year is "inability to obtain the full complement of men."

Many useful improvements have been, and are being, carried out in the interest of the public health. Of these, some of the most important are, the steps being taken to put an end to the practice of intramural burial, the closing of private slaughter-houses in inhabited and crowded localities, the opening out, by driving wide streets through them, of crowded, ill-ventilated parts of the town, the cleansing and regulation of bakeries, and the ventilation, drainage, and paving of cattle yards. None too soon, "a house-to-house inspection is being conducted in all the divisions with a view to mitigate "insanitary conditions. The plans submitted for the erection of buildings are thoroughly scrutinized "and no plan is passed which does not conform to the rules of sanitation as to drainage, ventilation, "latrine accommodation, &c." Altogether, it is clear that there is no lack of energy in the management of the Health Department of Madras. The want is the want of the funds needful to carry out the drainage and water improvement schemes which everybody knows to be necessary before any decided impression can be made on the persistent high mortality of the city.

29th May 1897.

No. 15.

Memorandum by the Army Sanitary Commission on the Administration Report of the Municipal Commissioner of Bombay for 1895–96.

1. The year 1895 was more favourable to the public health than its predecessor. The number of deaths decreased from a total of 27,330 in 1894 to 25,081, or from a ratio per 1,000 of population of 33·25 to a ratio of 30·52. The chief decrease is shown under the headings of Diseases of the Respiratory System, of the Digestive System, Cholera, and Small-pox. Under the head of Fevers the decrease was only slight.

2. The Health Officer attaches to his report a chart which shows very clearly that, when Bombay suffers from epidemic influences, these influences are not confined to the city, but simultaneously affect the country around. The separation of these general causes of sickness from local causes is important. Whilst the former are, in the present state of our knowledge, imperfectly understood, and mostly beyond human control, the latter can be measured by their effects and definite measures taken for their removal. The improvement in the health of Bombay during the year under notice was due, the Health Officer considers, to the absence of the former general causes of sickness, and not to any marked amelioration in local sanitary conditions. With prophetic foresight Dr. Weir writes:—"I cannot hope for further reduction in the mortality until the local insanitary causes that "I have so frequently described, and which I will once more describe so that there may be no "responsibility on me, are removed."

3. *Vital Statistics.*—The *births* of 15,684 living children were registered. These give a birth-rate of 19·08 per 1,000 of population. So low a ratio is accounted for by the disproportion of the sexes, there being in Bombay only 100 females to every 176 males. The Health Officer concludes from an examination of the registers of births according to class of the population that the birth-rate

is not far from correct. The chief increase in the rate has taken place amongst low-caste Hindus. The birth-rate amongst this rapidly increasing class was as high as 34·93 per 1,000 of population. As might be expected, the proportion of women to men in this class is higher than the proportion for the population of Bombay as a whole. Amongst the low-caste Hindus there are 100 females to every 134·96 males.

As already stated, the number of *deaths* gives a ratio of 30·52 per 1,000 of population. In the absence of any severe outbreak of epidemic disease the rate is a high one, and due without question to the operation of the insanitary conditions so repeatedly described by Dr. Weir. From cholera, only 90 deaths were registered, and from small-pox 270. On page 592 of the Report, a table gives the death-rate in each section of the city. This varies from 50·61 in 2nd Nagpadia to only 3·02 in the Water Division. The overcrowding in the former section is excessive, there being on the average 15 families, or 67·18 persons in each house.

4. *Chief Diseases.*—Of the total number of deaths, 6,404 were caused by *fevers*, as compared with 6,458 in the preceding year. The persistently high death-rate from fevers in Bombay is due to well-known conditions. "There has been an enormous increase in the water supply since 1892, "from 16½ million gallons to some 29 millions or more daily, and very little increase in the number "of drains. The island is flooded or irrigated with water, and unless drains are constructed to take "away all the water that comes into the city, the life of a healthy population will not be possible; "what has been seen in countries of marsh and wet, the poisoning of life from malarial fevers, will "be seen here."

Diseases of the Respiratory System, next to fevers, caused the greatest number of deaths, no fewer than 4,565 having been registered under this head. As might be expected, the mortality from these diseases is highest where overcrowding is greatest. In 2nd Nagpadia the ratio of deaths from diseases of the respiratory system was 10·28 per 1,000 of population, and in this section of the city overcrowding reaches its maximum.

Phthisis is credited with having caused 3,610 deaths. It owes its prevalence to much the same conditions as diseases of the respiratory system. This is well shown in the table on page 589 of the Report. Where these diseases were most fatal, as in 2nd Nagpadia, there, too, was phthisis most fatal.

Diarrhœa and Dysentery were considerably less fatal than during the preceding year. Between them they accounted for only 1,813 deaths, as compared with 2,344 in 1894, or rather more than the average of previous years.

Small-pox caused 270 deaths, against 531 in 1894. As usual, children under four years of age suffered most. And yet, when the returns of vaccination are examined, it is seen that, whilst the number of living children born during the year was 15,684, the number of those under one year of age who were successfully vaccinated was 14,470. If, from the number of children born, 6,683 who died before reaching one year of age be deducted, it will be evident that the remainder, 9,001, is greatly less than the total number successfully vaccinated under one year of age. The statistics of births and of vaccination go, therefore, to show that the mortality from small-pox amongst children under four years of age was not chargeable to neglect of infant vaccination.

The mortality from *cholera* was unusually small. Only 90 deaths were registered as due to this cause. It is worth noting that in the section of the town, 2nd Nagpadia, in which the death-rate from all causes was highest, there was but one death from cholera; whilst in the Water Division, in which the mortality from all causes was by far the lowest, there were seven deaths from this disease. In other words, the death-rate from cholera in the healthiest part of the town was ·31 per 1,000 of population, and in the unhealthiest, as estimated by the mortality, only ·05. Dr. Weir gives other interesting statistics regarding the incidence of this disease. He finds, for example, that 40 per cent. of the deaths occurred amongst persons living on ground floors. Last year, as many as 81·6 per cent. of all the cases occurred on ground floors. He likewise finds the same results as in former years, when the ages of those attacked are compared—a small number of cases with a light mortality at an early period of life, and an increasing mortality as years advance. The purity or impurity of the water supply, as estimated by analysis, does not seem to stand in any definite relation to the prevalence of cholera during the year. Both the Tulsi and Vehar supplies were most impure in April; during that month there were two deaths from cholera. "In July the Tansa "water was almost pure"; in the same month there were three deaths from cholera. So, likewise, when in December the Tulsi water from the Malabar hill was of more than the average good quality, the number of cholera deaths during that month was 10.

5. *Sanitary work.*—Although from year to year the Health Officer has felt himself compelled to set forth in the strongest terms the sanitary defects of Bombay, it must not be supposed that the executive authorities are not using their utmost efforts, with the means at their command, to remove these defects. They have already at vast expense provided their city with an abundant and pure water supply. Indeed, one of the complaints of the Health Officer is that, in the absence of a sufficient drainage system, the supply is too abundant. It must be not a little disappointing to the municipality to find that after this excellent supply has been provided, the annual revenue from water falls short of the expenditure by nearly two lakhs of rupees.

Drainage works, the most urgent sanitary need of the town, are vigorously pushed forward. On the Colaba sewerage works, over seven and a half lakhs had been expended at the close of the year. On five other important drainage works, sums of money, varying from 35,000 to upwards of two lakhs of rupees were expended. Two more drainage schemes were sanctioned and money provided for their execution, although they had not been commenced at the end of the year. And yet, "in more

" than half the island there are not drains." This shows that though much has been done and is being done, the condition of Bombay as regards drainage fully justifies the description given of it by Dr. Weir.

6. Recent events have shown that other sanitary improvements of a no less urgent nature than drainage are required in Bombay. The insanitary and overcrowded state of the houses in some sections of the town are a source of the greatest danger to the public health. This has not escaped the vigilance of the Health Officer. "It is deplorable," he writes, "that houses in the most crowded "portions of the city can be rebuilt without leaving on one side an open space for ventilation and "drainage. It seems of little avail having Building Byelaws when people can build where houses "are closest together, without leaving on one side a gully for open air, for light and for drainage. "Public attention is affected by the loss of life, however small, when a building falls, but here we "have, through imperfection in the Municipal Law, many people annually poisoned by foul air." In our Memorandum for 1894 on the Administration Report of the Commissioners of the town of Calcutta we invited attention to the site crowding with lofty, ill-ventilated houses which is permitted in that city. The remonstrances of Health Officers may for a time fail in their purpose; but sooner or later they will be driven home by events which will admit neither of question nor delay.

29th May 1897.

REPORT

ON

SANITARY MEASURES IN INDIA

IN

1896-97.

VOL. XXX.

Presented to both Houses of Parliament by Command of Her Majesty.

LONDON:
PRINTED FOR HER MAJESTY'S STATIONERY OFFICE,
BY DARLING & SON, LTD., 1-3, GREAT ST. THOMAS APOSTLE, E.C.

And to be purchased, either directly or through any Bookseller, from
EYRE & SPOTTISWOODE, EAST HARDING STREET, FLEET STREET, E.C.; and
32, ABINGDON STREET, WESTMINSTER, S.W.; or
JOHN MENZIES & Co., 12, HANOVER STREET, EDINBURGH, and

HODGES, FIGGIS, & Co., LIMITED, 104, GRAFTON STREET, DUBLIN.

1898.

[C.—9111.] *Price* 2*s*. 0½*d*.

SALE OF GOVERNMENT PUBLICATIONS.

The under-mentioned Firms have been appointed sole Agents for the sale of Government Publications, including Parliamentary Reports and Papers, Acts of Parliament, Record Office Publications, &c., &c., and all such works can be purchased from them either directly or through retail booksellers, who, under the provisions of the sale agency contracts, are entitled to a discount of 25 per cent. from the selling prices :—

IN ENGLAND :—

For all publications *excepting* Ordnance and Geological Maps, the Hydrographical Works of the Admiralty, and Patent Office Publications :—MESSRS. EYRE AND SPOTTISWOODE, East Harding Street, E.C.

For Geological Maps :—Mr. E. STANFORD, Cockspur Street, S.W.

For Hydrographical Works of the Admiralty :—Mr. J. D. POTTER, 31, Poultry, E.C.

Patent Office Publications are sold at the Patent Office.

For all publications *excepting* the Hydrographical Works of the Admiralty and Patent Office Publications.

IN SCOTLAND :—MESSRS. JOHN MENZIES & Co., 12, Hanover Street, Edinburgh, and 90, West Nile Street, Glasgow.

IN IRELAND :—MESSRS. HODGES, FIGGIS, & Co., LIMITED, 104, Grafton Street, Dublin.

The following is a list of some of the more important Parliamentary and Official Publications recently issued :—

Parliamentary:

Statutes—

Public General, Session 1898. With Index, Tables, &c. &c. Roy. 8vo. Cloth. Price 3*s*.

Second Revised Edition. By a A.D. 1714–1800. Vol. III. A.D. 1801–1814. Vol. VI. A.D. 1837–1842. Vol. VII. A.D. 1843–D. 1852–1857. Vol. X. A.D. 1858–1862. Vol. XI. Vol. XIII. A.D. 1872–1875. Price 7*s*. 6*d*. each.

Revised Editions. Tables show 1 Vict. 1897. Price 6*d*.

Statutes in Force. Chronologi To the end of 58 & 59 Vict. 2 vols. Roy. 8vo. Price 10*s*. 6*d*.

The Statutory Rules and Orders those of a local, personal, or temporary character, issued Price 10*s*. each.

A. GODLEY,
Under Secretary of State for India.

INDIA OFFICE,
13*th December* 1898.

REPORT.

The present Report on Sanitary Measures in India during the year 1896 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1896.

The health of the European troops on service in India during 1896 was on the whole satisfactory. On an average strength of 70,484, the admissions into hospital were in the ratio of 1,387 per 1,000, against 1,462 in 1895, the daily sick-rate was again 94, and the death-rate fell from 15·26 to 14·84. The invaliding ratio (28) was higher by 5 per 1,000, so that the total loss by death and invaliding was equal to 43 per 1,000, an increase of 4 per 1,000 on the previous year.

The Presidential Army system was abolished in 1894, and the whole of the forces in India is now designated the Army of India, divided into the Bengal, Punjab, Madras, and Bombay Commands. This organization took effect from the 1st April 1895.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands during 1896 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1896	22,457	1,436	100	18·70	29	48
	1895	22,259	1,436	98	16·98	26	43
Punjab	1896	18,823	1,282	84	13·60	26	40
	1895	19,733	1,519	92	20·02	18	38
Madras	1896	13,488	1,336	99	9·79	33	43
	1895	13,417	1,227	91	8·79	31	40
Bombay ...	1896	15,716	1,485	92	15·14	24	39
	1895	15,622	1,627	92	12·35	21	33
INDIA ...	1896	70,484	1,387	94	14·84	28	43
	1895	71,031	1,462	94	15·26	23	39

It will be seen from the above statement that of the four Commands Bengal had the highest daily sick and death rates. The Madras Command was the healthiest, and its death-rate was not much more than half that of Bengal.

The chief causes of sickness in the whole European Army were, as in the year 1895, venereal diseases and ague, the former yielding a ratio of 512 per 1,000 against 522 in 1895, and the latter 239 per 1,000 against 336. More than half (54 per cent.) of the total sickness resulted from these two causes. Enteric fever, as usual, was the chief cause of mortality, and the death-rate from it was 6·31 per 1,000 against 6·72 in 1895. This fever yielded 43 per cent. of the total deaths.

Groups of stations.

The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,310	1,469	116	11·45
Burma, Inland	2,679	1,593	111	5·60
Bengal and Orissa	2,460	1,302	80	17·07
Gangetic Plain and Chutia-Nagpur	7,492	1,394	101	22·42
Upper Sub-Himalayan	14,390	1,341	92	13·83
Indus Valley and North-Western Rajputana...	4,837	1,669	95	14·47
South-Eastern Rajputana, Central India, and Gujarat.	6,440	1,756	120	19·72
Deccan	10,157	1,317	90	14·67
Western Coast	1,556	1,110	78	17·99
Southern India	3,561	1,209	78	11·23
Hill Stations	8,776	1,209	90	12·53
Hill Convalescent Depôts	3,591	1,197	88	12·53

Of the above 12 groups, five returned a higher daily sick-rate than the ratio for the whole European Army, the highest being 120 per 1,000 of average strength in South-Eastern Rajputana, Central India and Gujarat group. The two Burma groups followed with ratios of over 110, and the Gangetic Plain and Chutia-Nagpur next with 101. The lowest ratios (78) were returned by the Western Coast and Southern India groups. The death-rate of the entire Army was exceeded by four groups, viz., the Gangetic Plain and Chutia-Nagpur, South-Eastern Rajputana, &c., Western Coast and Bengal and Orissa groups.

Of the stations with a strength of over 1,000, four returned death-rates above 20 per 1,000, viz., Allahabad 37·61, Fyzabad 23·93, Lucknow 20·42, and Agra 20·37.

Cholera. The mortality from cholera in the European Army was higher than in 1895. The admissions to hospital from the disease numbered 70 or 1·0 per 1,000 of average strength, against 44 or 0·6 per 1,000 in 1895, and the deaths rose from 32 or 0·45 per 1,000 to 63 or 0·89.

Small-pox. Among the whole of the European troops in India there were during the year under notice 122 cases of small-pox ; of these ten were fatal. In the previous year there were only 19 cases and two deaths.

Fevers. From intermittent fever the admissions to hospital among the European troops in 1896 were in the ratio of 239 per 1,000 of strength against 336 in the previous year. The deaths under this head numbered 7, a decrease of 11 on the mortality of 1895. Of these, 5 occurred among troops in the Bengal Command and 2 among those in the Bombay Command.

From enteric fever the admissions fell from 1,870 or 26·3 per 1,000 of strength to 1,795 or 25·5, and the deaths from 477 or 6·72 per 1,000 to 446 or 6·31. Of the four Commands Bengal recorded the highest mortality under this head, viz., 7·70, followed by Bombay with a ratio of 6·36, Punjab 6·11, and Madras 4·23. Among the larger stations with an average strength of over 1,000, Allahabad returned a death-rate from this fever of 27·20, Fyzabad 12·96. Agra 12·40, Peshawar 10·72, Ranikhet 10·58, and in six other stations the ratios ranged from 9·50 to 6·92. As usual, young and unacclimatised soldiers were the chief sufferers ; among those under 25 years of age the death-rate was 9·52 per 1,000 against 8·22 in 1894, while among men between 25 and 29, and from 30 to 34, the mortality was 3·24 and 2·18 per 1,000 respectively. Among men of less than one year's residence in India the death-rate from this fever was 14·40 per 1,000, among men between one and two years 8·59, and among troops between five and ten years' service the rate was 2·44 per 1,000.

Bowel complaints. The admissions from dysentery and diarrhœa among the European troops were in the ratio of 46 per 1,000 of strength, or 13 per 1,000 less than in 1895. The mortality from dysentery was in the ratio of 0·67, and from diarrhœa 0·01 per 1,000. Dysentery was most prevalent in the Madras Command.

Venereal diseases, as usual, came first in the list of causes of admission to hospital ; and also in the causes of invaliding. They were the cause of 37 per cent. of the total sickness during 1896, and over 24 per cent. of the invaliding of the European Army of India. The ratio of admissions from venereal diseases per 1,000 of strength was 512 or 10 below that of 1895. This is vastly in excess of the ratio of most continental armies, and also of the ratios of British troops in most other parts of the world. The admission-rate under this head was highest in the Bengal Command, viz., 582 per 1,000, next came Bombay with a ratio of 537, Madras with 526, and the Punjab with 395, but only in Bombay was there an increase. The number of men constantly sick in hospital from these diseases was 3,162, against 3,165 in the previous year, being equivalent to over three regiments ; and the average stay of a case in hospital in each year was about 32 days. The mortality under this head was 14, and the invalidings 479, against 15 and 353 respectively in 1895. Dr. Cleghorn, Sanitary Commissioner with the Government of India, in his report for the year under notice, again furnishes figures "showing clearly " how the arrival year by year of fresh batches of young unmarried men under the short " service system has been accompanied by an increase of venereal disease. Since 1878 " the number of fresh troops arriving in the country has, as a rule, been much greater " than before. The gradual rise in the percentage of men under 25 years of age in " the army, and of men under five years' Indian service has been pretty uniform, as " has been the well-marked decline in the number of married men ; and the same " may be said of the gradual rise in the venereal ratio. As youth and recent arrivals " have become more common in the army, venereal disease and enteric fever have not " unnaturally increased in frequency of occurrence." Statistics also show "a more or " less continuous rise, especially since the year 1884 ; and the ratio of secondary syphilis " is the highest on record. This is a condition of things which is sure to tell when the men " have to go on field service." Venereal diseases.

The loss to the whole army by invaliding during 1896 amounted to 1,966 men, equal to 27·89 per 1,000, against 1,663 or 24·82 in 1895. The proportion of invalids to strength was highest in the Madras Command (33·2), followed by Bengal (29·2), Punjab (25·7), and Bombay (24·1). Of the total number invalided, 39 per cent. were discharged as unfit for further service, being 6 per 1,000 higher than in 1895. As regards the influence of age and length of residence in India upon invaliding, 62 per cent. of the total number invalided were under 25 years of age, against 60 in 1895, while 40 per cent. were of less than two years' service, and 85 per cent. were of less than five years' service. In the European Army as a whole 82 per cent. of the total strength had seen less than five years' service. Invaliding.

II.—NATIVE ARMY.

Sickness and mortality in 1896.

There was less sickness and mortality in the Native Army of India during 1896 than in 1895, which is attributed to the dry and non-malarious character of the year.

The ratios of sickness and mortality among Native troops in the six Commands during 1896 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1896	26,279	809	31	8·52
	1895	24,454	790	30	8·26
Punjab	1896	38,824	766	29	14·37
	1895	41,062	878	33	17·58
Madras	1896	25,009	665	31	8·04
	1895	26,738	660	30	8·38
Bombay	1896	24,707	880	28	8·82
	1895	25,259	889	28	11·12
Corps of Central India and Rajputana	1896	5,062	630	20	10·47
	1895	5,172	595	21	6·77
Hyderabad Contingent	1896	6,970	563	19	7·03
	1895	6,968	617	22	5·74
INDIA	1896	128,826	763	29	10·20
	1895	129,655	794	30	11·60

Of the six Commands the Punjab was again the most unhealthy, though the figures show an improvement on those of 1895. Pneumonia was very prevalent in this force, and the death-rate from it was 6·21 per 1,000, or nearly half of the total mortality.

The chief cause of sickness in the Native Army was ague, which again yielded 36 per cent. of the total admissions. Among the diseases from which the admissions to hospital were higher than in 1895 were influenza, cholera, small-pox, and venereal diseases; while from fevers, pneumonia, other respiratory diseases, and dysentery and diarrhœa, there was a decrease in the admissions. There was more influenza among the Native troops in 1896 than there had been since 1892, and the admission-rate rose from 7·0 per 1,000 of average strength in 1895 to 10·7. From venereal diseases the admission-rate in the Native Army was only 37·2 per 1,000 of strength, as compared with 512 per 1,000 among European troops. Figures under this head are not available for the years before 1877. The ratios run at a much lower level than those of European troops, and there is not the same tendency to increase. Only once since 1877 has the ratio reached 40 per 1,000, that was in 1890, when the admission-rate was 41·1.

Respiratory diseases were the chief causes of death in the Native Army, and no less than 36 per cent. of the total deaths were due to them. The death-rate under this head was 3·72 per 1,000 of average strength, against 4·87 in 1895. From pneumonia alone the mortality among the Native soldiers (3·14 per 1,000) was about five times as great as that among European troops (0·64 per 1,000). Fevers of all kinds were the cause of 16 per cent. of the total deaths, against 46 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 1·58 per 1,000, while among the European troops the proportion was 0·50. On the other hand, the death-rate from enteric fever among the Native troops was only 0·04 per 1,000, as compared with 6·31 among the European troops. From cholera there were 88 deaths in the Native Army, equal to 0·69 per 1,000 of strength, as compared with 53 and 0·41 respectively in 1895.

The following statement gives the principal statistics of the Native Army arranged in geographical groups for 1896 :— Groups of stations.

	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	2,324	476	20	6·88
Burma, Inland	6,680	982	46	11·08
Assam	1,774	1,149	45	21·98
Bengal and Orissa	3,113	868	36	7·71
Gangetic Plain and Chutia-Nagpur	6,780	598	25	5·46
Upper Sub-Himalayan	16,176	610	24	11·07
Indus Valley and North-Western Rajputana...	14,776	820	27	17·66
South-Eastern Rajputana, Central India, and Gujarat.	12,283	713	26	9·04
Deccan	20,434	785	26	7·34
Western Coast	2,713	607	27	9·89
Southern India	8,736	578	29	7·67
Hill Stations	17,071	1,035	39	10·25

In four of the above groups the daily sick-rate was higher than that for the whole Native Army, and in five the mortality was greater. The highest mortality was that of the Assam group (21·98), which shows an increase of 7·81 per 1,000 on the rate for the previous year.

Of the large stations with a strength of over 1,000, the following recorded the highest death-rates: Nowshera 37·77 per 1,000 of average strength, Manipur 37·66, Peshawar 21·34, Kohat 19·25, and Dera Ismail Khan 19·19.

III.—GENERAL POPULATION.

Vital statistics.

Births were registered throughout all the 10 provinces in India in 1896, and the birth-rates varied between 43·0 and 26·62 per 1,000 of population under registration. The best results were obtained in the Punjab, Berar, Bengal, Bombay, the North-Western Provinces and Oudh, and Assam, their respective rates being 43·0, 38·3, 38·0, 36·7, 35·4, and 33·6. In the remaining provinces the birth-rates ranged between 32·2 in Lower Burma and 26·62 in Coorg. In seven provinces the birth-rates were higher than in the previous year, and in three they were lower. The birth-rates exceeded the death-rates in seven provinces, the excess per 1,000 varying between 11·5 in the Punjab and 0·19 in Coorg. The climatic conditions of the year were not favourable to health, and the recorded deaths rose from 6,163,743 or 28·94 per 1,000 of registered population in 1895 to 6,779,016 or 32·05. With the exception of Berar and Coorg, the mortality recorded in the several provinces was higher than in 1895. Of the chief diseases, cholera was much more prevalent, and the total number of deaths from it rose from 310,797 to 469,667. The increase was spread over eight of the provinces, but the Central Provinces was the chief sufferer, the death-rate from this cause being 5·58 per 1,000, against 1·63 in 1895. There was an increase also in the deaths from fevers, which was participated in by all the provinces except Berar, Madras, and Coorg. In connexion with this cause of death the scheme for the sale of quinine at a low price by postal agency was making steady progress. The mortality from dysentery and diarrhœa was slightly lower than in the previous year; but from small-pox there was an increase of 88,456 deaths.

The deaths from the chief diseases and from all causes in the several provinces were as follow:—

	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Deaths from all Causes.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000 of Population under registration.

Bengal.

The year 1896 in Bengal was particularly unhealthy. The rainfall being deficient and unseasonable affected the crops, resulting in widespread scarcity and high food prices. The birth-rate was higher, though still considerably below the estimated birth-rate for India of of 48·8 per 1,000. The number of births registered in the province rose from 2,458,623 or 34·59 per 1,000 of population in 1895 to 2,703,486 or 38·03, the latter being made up of district rates varying from 48·98 in Noakhali and 47·02 in Faridpur to 25·82 in 24-Parganas. Of the 46 districts there was an increase of births in 38, the greatest advance being in Cuttack, where the ratio was 13·26 per 1,000 in excess of the previous year. Faridpur came next with an increase of 10·45, followed by Dacca with an increase of 8·61, and Monghyr of 8·10. In seven other districts there was an improvement ranging from 7·81 to 5·64 per 1,000. In rural areas the birth-rate was 38·64 per 1,000, and in towns 26·18, as compared with 35·13 and 23·91 respectively in 1895. Out of 147 towns only 11 returned a birth-rate in excess of 40 per 1,000, while 22 rural areas returned rates of over 50 per 1,000, and 63 others over 45 per 1,000.

The total number of deaths registered during the year under notice was 2,428,830 or 34·17 per 1,000, as compared with 2,231,458 or 31·39 in 1895. There was thus an excess of births over deaths of 274,656 or 3·86 per 1,000. The district death-rates ranged from 51·43 in Darjeeling to 23·75 in Sonthal Parganas. In urban areas the rate of mortality rose from 34·46 to 36·14, which was made up of ratios varying from 58·30 in the small municipality of Bhadreswar in Hooghly to 15·70 in the municipality of Maniktola in the 24-Parganas. Twenty-two out of the 147 towns returned a death-rate in excess of 44 per 1,000, while 19 returned rates below 25 per 1,000. "In a year of "general unhealthiness like that under report," the Sanitary Commissioner (Dr. Dyson) remarks, "it is probable that in most of the districts of the province the death-rate "was very near, if not in excess of, the normal estimate of 44 per 1,000. I am afraid, "therefore, that in those places which have returned low rates, there is no other "explanation than defective registration." In rural areas the death-rate rose from 31·24 to 34·07, the highest mortality for such areas being recorded in the districts of Darjeeling (53·07), Muzaffarpur (46·75), Backergunge (44·07), Darbhanga (41·58), Patna (41·19), Rajshahi (40·49), Jailpaiguri (40·0), and Champaran (40·0), cholera and fevers being the chief causes of these high rates.

Of the chief death causes cholera was widely prevalent in 1896, and the number of deaths registered from it was 226,824, or 3·19 per 1,000, against 177,087 or 2·49 in 1895. Every district was affected by the disease, but the mortality varied greatly, and the number of villages attacked was 27,460, or 12·23 per cent. of the total, against 24,103 or 10·72 per cent. in 1895. Eight districts recorded cholera death-rates of over 5 per 1,000, viz., Muzaffarpur (8·78), Balasore (7·72), Howrah (6·73), Nadia (6·52), Darbhanga (6·24), 24-Parganas (5·83), Khulna (5·72), and Calcutta (5·06); in 26 other districts the rates ranged from 4·75 to 1·15, and in ten districts the rates were below 1 per 1,000. As regards the seasonal incidence of the disease in each of the main geographical divisions of the province, the seasons of highest mortality in Bengal proper and Orissa were March and April. In Behar the rates were highest in May and June; and in Chota Nagpur in May, June, and July. During the year, Dr. Haffkine, with a special staff, was engaged under the Bengal Sanitation Department, in cholera inoculation. A large number of people were inoculated, but "it is difficult to form a confident opinion as to its results "until statistics of its working have been collected on a large scale."

From small-pox the mortality was higher than in 1895, the number of deaths having risen from 13,020 or 0·18 per 1,000 to 13,388 or 0·19 in 1896, an insignificant rate, however, when compared with those from other diseases prevalent in Bengal. The disease was present in all the districts except Khulna, but the only district in which it can be said to have prevailed in an epidemic form is Patna, where the death-rate was 1·20. This district is reported to be very backward in vaccination, and to this cause the high rate of mortality is attributed.

No less than 71 per cent. of the total deaths were recorded under fever, a term which, Dr. Dyson observes, "covers a multitude of complaints in the minds of the village "chaukidar, who is primarily responsible for registration, and it is certain that numerous "deaths are put down to fever which are really due to other causes." The number of deaths reported to have occurred from fever during the year was 1,760,225 or 24·76 per 1,000 of population, against 1,634,254 or 22·99 in 1895. Just over a half of the 46 districts recorded a higher fever mortality than the provincial rate, ten registering a rate over 30 per 1,000. Dr. Dyson says:—"In a year of abnormal meteorological "conditions, such as that under report, when the rainfall was intermittent, and the drying "and wetting of the soil alternate, a high death-rate from fever is a natural consequence. "Thus in most of the districts there was a greater mortality from this cause in 1896 than "in the previous year. As regards the districts that head the list, the fact that they are "subject to the notoriously deadly Terai fever, probably in a great measure explains the "exceptionally high death-rate in them."

From dysentery and diarrhœa 47,935 deaths were registered, equal to 0·67 per 1,000 of population, against 49,871 or 0·70 in the previous year. Of the districts, Darjeeling returned the highest death-rate from these causes (6·69), Howrah came next (4·85), followed by Calcutta (4·35), Balasore (3·25), and Puri (2·57). These five districts have headed the list, though in a different order, for the last four years. The Sanitary Commissioner, however, believes the returns are to a great extent vitiated by deaths from these causes being returned as deaths from fever by the native recorders of vital statistics.

In Calcutta the birth-rate rose from 16·0 per 1,000 in 1895 to 18·4 in 1896. The deaths fell from 27,031 or 39·6 per 1,000 in 1895 to 24,356 or 35·7 in 1896. The decrease

in mortality was due to fewer deaths from fever and small-pox. Cholera was more prevalent than in the previous year, and the deaths from it rose from 2,090 to 3,449. Professor Haffkine's method of inoculation as a prophylactic against the disease was again carried on during the year, and 2,500 operations were performed. There were only 69 deaths from small-pox, as compared with 2,220 in 1895. The deaths from fever were also fewer, the total being 9,564, equal to 14·0 per 1,000 of population, against 11,345 or 16·6 in the previous year. The deaths from dysentery and diarrhœa declined from 3,269 in 1895 to 2,967 in 1896.

North-Western Provinces and Oudh.

Notwithstanding the scarcity and distress which prevailed in certain parts of the North-Western Provinces and Oudh during 1896, the year was fairly healthy. The meteorological conditions of the year were a deficient rainfall and abnormally high temperature, though the dryness of the season was beneficial in districts which usually suffer from effects of excessive moisture. The general inferiority of the autumn and spring harvests, following the poor out-turn of the two preceding years, exhausted to a large extent the resources of the population, and famine being prevalent it became necessary to undertake relief works in several districts.

During the year 1,660,387 births were recorded, giving a ratio of 35·40 per 1,000 of population, as compared with 1,637,235 or 34·90 in 1895. Of the total 48 districts 25 showed a birth-rate above and 23 below the average of the provinces. Etah headed the districts with a birth-rate of 52·76, followed by Bulandshahr 51·14, Agra 49·57, Aligarh 49·49, and seven others recorded rates of over 40 per 1,000. The birth-rate in municipalities was 39·30 against 39·37 in the previous year, and was made up of extremes ranging from 61·41 in Fatehpur-Sikri to 26·44 in Lalitpur. In rural areas the birth-rates ranged from 71·65 in Rasulpur in Muttra district to 10·91 in Kotdwara in Garhwal, the average being 34·91 against 34·29 in 1895.

The number of deaths registered rose from 1,366,443 or 29·13 per 1,000 of population in 1895 to 1,562,894 or 33·32, which was made up of district rates ranging from 67·40 in Jhansi to 22·32 in Azamgarh. The provincial death-rate was exceeded in 22 districts. The town death-rate was 39·11 against 33·46 in 1895, and the rural death-rate 32·59 against 28·58. In several municipalities the rate of mortality was considerably above the average; but the Sanitary Commissioner (Surgeon-Major Thomson) points out that "the "value of the figures as an indication of the sanitary condition of the locality and the "health of the inhabitants is in many instances disturbed by the fact of the existence of "poor-houses, to which many of the famine-stricken occupants came only to die." Nineteen districts and 44 municipalities recorded more deaths than births. Registration was again tested by local authorities, and the results disclosed an omission of 2·73 per cent. on 144,049 births, and 2·37 on 130,219 deaths; and in cases tested by the Vaccination Department the omitted percentages were 1·34 of births and 0·73 of deaths.

Of the chief diseases, cholera was fatal in 17,585 more cases than in 1895, the total deaths from the disease numbering 69,147 or 1·47 per 1,000, as compared with 51,562 or 1·10. Though not excessive, the mortality was considerably above the average, and in some districts the incidence of disease was very severe, especially in Jhansi, Banda, Bareilly, and Naini Tal, with death-rates of 8·95, 5·88, 4·15, and 4·10 respectively. In Banda an outbreak occurred among the people gathered on relief works, and in spite of the exertions made to maintain a pure water supply and efficient sanitary arrangements, and to prevent overcrowding, the disease abated only on their dispersal. More deaths from cholera were recorded in September than in any other month, the number reaching 12,926, which was also almost reached in May (12,480). The disease rapidly declined with the cold weather, and almost entirely disappeared in December, when only 226 deaths were reported. All the large fairs in the province passed off without the appearance of epidemic disease.

From small-pox there was a considerable rise in mortality, the deaths reaching 42,771 or 0·91 per 1,000 against 1,968 or 0·04 in 1895. An increase was anticipated by Dr. Thomson on account of the large proportion of the population being still unprotected. Children were the chief sufferers, though a large number of adults succumbed, among whom Dr. Thomson states, "no doubt were many persons who had been vaccinated, but "in whom the effect of the preventive virus had worn out. The remedy of course is "revaccination, and great efforts have been made to extend such operations. But con-"siderable difficulty is experienced in persuading adults to submit to revaccination, "principally because it temporarily cripples them and prevents them following their "usual occupations." The highest district death-rates from small-pox were 4·10 in Allahabad, 3·85 in Unao, 2·39 in Bareilly, and 15 other districts recorded ratios of over 1 per 1,000.

To fevers were ascribed 77 per cent. of the total deaths. The mortality from fever in 1896 was much higher than in 1895, the number of deaths having risen from 1,093,212 or 23·31 per 1,000 to 1,205,964 or 25·71. Among the districts, Pilibhit came first with a fever death-rate of 48·11, followed by Naini Tal (which includes the malarious Tarai) with 45·48, and Bareilly and Hamirpur with 40·88 and 40·54 respectively. Five other districts recorded ratios over 35 per 1,000, five over 30, and 12 over 25. The mortality was higher in every month up to September than during the same period in a normal year, but much lower in the three following months than it usually is. This is attributed to the fact "that many districts in a normal year severely visited by malaria in the "autumn, escaped this year (1896) with very little mortality from this cause."

The deaths from dysentery and diarrhœa during 1896 numbered 40,858, a decrease of 1,920 on the mortality of the previous year, the death-rates being 0·87 and 1·00 respectively. As usual, the hill tracts suffered most. High but not excessive rates were also recorded by Jhansi, Hamirpur, and Banda, and were attributed to large numbers of the people in these districts living on relief works in temporary huts. Kashipur town, in Naini Tal district, again had an exceptional amount of dysentery and diarrhœa, and its death-rate under this head was 16·37 against 12·84 in the previous year.

Though the year 1896 in the Punjab was not a year of plenty it was comparatively healthy. The number of births registered was 884,692 or 43·04 per 1,000 of population, as compared with 901,584 or 43·86 in 1895. The birth-rate was still higher than that of any other province in India, and was made up of district ratios ranging from 51·9 in Gujranwala to 17·4 in Simla and 30·0 in Peshawar. Further improvement was made in the registration of births in the frontier districts. The provincial birth-rate exceeded the death-rate by 11·5 per 1,000 of population, and in ten districts the excess was very considerable ranging between 22·5 and 16·2 per 1,000; while there were only three districts (Umballa, Kangra, and Simla) in which the deaths exceeded the births. **Punjab.**

From all causes 648,099 deaths were registered during the year, giving a death-rate of 31·53 per 1,000, against 601,972 or 29·29 in 1895. The highest district rates were reported from Umballa 40·9, Karnal 40·4, Kangra 40·3, and Rawalpindi 39·6, the remainder varying between 36·3 in Delhi and 22·9 in Gujrat. Although there was scarcity throughout the province in the latter part of the year, owing to deficient rainfall, there were only three deaths from actual starvation. "The preparations to meet any widely-"spread famine were timely," the Sanitary Commissioner, Dr. Roe, states, "and relief "was afforded to many persons who otherwise would have felt the high prices of grain "very severely."

Of the principal diseases, cholera was more prevalent in 1896 than in the previous year, the number of deaths having risen from 549 or 0·03 per 1,000 to 5,146 or 0·25. Nine of the 31 districts were free from the disease, and in the remainder it was severe only in Rawalpindi district, where 2,374 occurred, being equal to a death-rate of 2·38 per 1,000. Cholera is reported to have spread by means of human intercourse from the Nurpur fair, about eight or nine miles from the town of Rawalpindi. "Whatever may have been its "mode of introduction at the fair," Dr. Roe states, "the disease by the dispersion of the "pilgrims spread rapidly all over the district of Rawalpindi and the neighbouring one of "Peshawar." With the exception of a single case of cholera, which was taken out of the train at Ludhiana in April, the entire province was quite free from it until May, in which month 1,245 deaths were recorded, falling in June to 1,206, and each other month, until in November there were only 33 deaths and in December one.

The province was visited by a most severe epidemic of small-pox during the year, resulting in a mortality of 45,084 and a death-rate of 2·19, which is the highest reached in any year since 1879, when the deaths numbered 59,489, and the death-rate amounted to 2·83. The epidemic broke out in a virulent form in December 1895, when 2,088 deaths were reported; the number increased each month until May, when the maximum of 8,047 was reached. From that month there was a steady fall in the mortality until the cold weather set in, when the mortality began to rise again. All the districts were affected, but the epidemic was most fatal in Ferozepore, with a death-rate of 5·75 per 1,000, followed by Gurgaon, Umballa, Montgomery, and Shahpur, with ratios of over 4 per 1,000 each, and by five others whose death-rates were above 3 per 1,000. Of the total 45,084 deaths from this disease 29 per cent. were infants under one year of age, and 59 per cent. were children between the ages of 1 and 12, facts which show that a large number of children must have been unprotected. Steps have been taken with the view of increasing vaccination in the districts of greatest small-pox mortality.

The deaths ascribed to fevers numbered 393,535, giving a death-rate of 19·15 per 1,000, against 392,118 or 19·08 in 1895. The provincial rate was exceeded by 16 out of the

total 31 districts, the highest being Kangra 29·16, Umballa 25·74, Rawalpindi 25·20, and Rohtak 24·55, the remainder ranging from 23·66 in Karnal to 9·08 in Montgomery. In January, nearly twice as many deaths were recorded under this head than in any other month of the year. "This curious fact," Dr. Roe observes, "appears to be due chiefly to "erroneous classification, for from my personal experience of the province I feel satisfied "that the majority of deaths reported in January as due to fevers were really caused by "pneumonia and chest complaints. Wherever a rise in temperature is observed it is simply "called 'fever' by the ignorant villager, and reported as such, and until our system of "disease and death registration is much more perfect we must be content to accept "'fever' as a general term including a large proportion of purely chest disorders."

From dysentery and diarrhœa 13,886 deaths were registered, being equal to 0·68 per 1,000 of population, against 15,648 or 0·76 in 1895. Twelve districts recorded a higher mortality under this head than the provincial rate, the highest being Simla 3·26, Gurgaon 1·41, Kangra 1·27, Delhi 1·25, Gurdaspur 1·09, Umballa 1·00, Karnal 0·99, and Hissar 0·91.

Central Provinces.

The year 1896 in the Central Provinces was one of exceptional drought and failure of the crops, "which had a disastrous effect on the public health and the prosperity of the "people." Owing to the failure of the rabi harvest and consequent high price of food relief operations became necessary early in the year, and until its close large remissions and suspensions of revenue and rent were granted. The vital statistics of the year were the most unfavourable ever recorded. The registered births were fewer by 16,005 than in 1895, the number having declined from 317,432 or 33·41 per 1,000 to 301,427 or 31·72, the lowest rate recorded since 1881, and the lowest of all provinces in India except Madras. In 14 of the 20 districts fewer births were registered than in the previous year, and in the six showing an increase the numbers had considerably declined in 1895 on the figures of 1894. Various reasons have been adduced for the decrease. "It is remarkable," the Chief Commissioner remarks, "how closely the maximum falling-off in the birth-rate corresponds "with the area of maximum harvest failure and consequent distress. It would seem that "a remarkably short birth-rate may be expected as almost conclusive evidence of the "prevalence of pressure on the labouring population."

The deaths of the year numbered 468,469 or 49·31 per 1,000, against 349,137 or 36·75 in 1895. This high mortality has only once been approached within the previous ten years, the death-rate of 1889 having been 43·79 per 1,000. In both years the abnormal mortality was in great part due to widespread and destructive epidemics of cholera and fever. The provincial death-rate was exceeded in seven districts, viz., Damoh (88·28), Mandla (73·68), Saugor (72·63), Jubbulpore (63·16), Seoni (61·94), Narsinghpur (55·48), and Balaghat (49·99). In these districts distress was prevalent, culminating towards the end of the year in acute famine.

The meteorological features of the year were also favourable to the development of the chief diseases from which the people suffered. Owing to the exceedingly dry and hot spring and summer cholera was exceptionally prevalent, and was fatal in 52,985 cases as compared with 15,506 in 1895, the death-rates being 5·58 and 1·63 respectively. The disease prevailed in every district of the province, but it was most severe in Mandla (15·75), Bilaspur (10·99), Damoh (9·58), Seoni (9·48), and Raipur (9·00). Only in the two districts of Hoshangabad and Burhanpur was the mortality less than 1 per 1,000. May and June were the most fatal months, when 12,935 and 14,000 deaths were recorded.

From small-pox the deaths rose from 6,644 or 0·70 per 1,000 in 1895 to 7,747 or 0·82. The disease was widespread and affected every district without exception. In proportion to population the districts of Wardha, Chandla, Betul, Seoni, and Bhandara suffered most, their ratios of mortality being 2·63, 1·78, 1·47, 1·35, and 1·30 respectively. In no other district was the mortality above 1 per 1,000. The disease prevailed with the greatest intensity in the hottest month (May) of the year, and declined with the approach of the rains, and this is the general experience of other provinces. Of the total small-pox deaths one-fourth occurred among infants, and nearly a half were children under 12 years of age.

Nearly 60 per cent. of the total deaths were ascribed to fevers, and the number registered during the year was 280,760 or 29·55 per 1,000 of population, against 221,418 or 23·30 in 1895. The provincial death-rate from fever was exceeded by ten districts, with ratios of mortality ranging from 58·11 to 31·34. The average town death-rate under this head was 22·65, against 19·32 in the previous year. The unseasonable drought of the months of September and October favoured the development of fevers to an unusual degree, "and "it is certain," it is stated, "that forms of disease classed under this denomination

" prevailed to an exceptional extent, not only among those who suffered from privation, " but among the well-to-do as well, during the last quarter of the year."

From dysentery and diarrhœa the registered mortality rose from 20,316 or 2·14 per 1,000 of population in 1895 to 29,882 or 3·14. It is pointed out that during seasons of scarcity bowel complaints are always exceptionally prevalent, when the poor resort to unwholesome and unsuitable food. The highest death-rate under this head was recorded by the Jubbulpore district (9·79), followed by Damoh (9·36), Murwara (9·18), and Mandla (7·68).

Progress continues to be made in Burma in the registration of births and deaths. In the area under registration in Lower Burma 145,688 births were recorded in 1896, giving a birth-rate of 32·27 per 1,000 of population, as compared with 131,147 or 29·04 in 1895. That there is still much room for improvement is shown in the variations in the district rates, which ranged from 42·84 in Pegu to 17·91 in Rangoon. The number of deaths registered was 106,687, giving a death-rate of 23·63 per 1,000 of population, against 101,160 or 22·40 in 1895. By districts the ratios ranged from 16·76 in Mergui to 36·31 in Rangoon. The Sanitary Commissioner (Dr. Sinclair) notices that rural circles returning a low birth-rate usually return a low death-rate, and *vice versa*. " Of " course, infant mortality in prolific communities," he says, " especially in this province " where so little care is taken of the young, must contribute largely to the general death- " rate ; but fertility testifies to prosperity and health, and it is more than probable that " these low birth-rates and low death-rates are largely due to careless registration. " Greater accuracy can hardly be expected from an unpaid agency, but improvement is " expected as the system of appointing ward headmen as registrars becomes general." Burma.

Of the chief causes of mortality that from cholera was much less severe than in 1895, the number of deaths being only 2,959 or 0·66 per 1,000, as compared with 5,150 or 1·14. All the districts except Kyaukpyu and Mergui were affected, and Thayetmyo and Sandoway had only one death each, but the deaths were highest in those of Bassein (596), Myaungmya (441), Thongwa (430), Henzada (410), and Hanthawaddy (289). The disease was present throughout the year, the months of greatest mortality being May, June, and July, when 419, 439, and 598 deaths were respectively recorded. Out of 35 towns 15 escaped cholera altogether. It is reported that nowhere in Upper Burma did the disease appear in an epidemic form during the year.

Deaths from small-pox were slightly more numerous than in 1895, viz., 1,669 or 0·37 per 1,000, against 1,540 or 0·34. Of these, 247 were infants and 814 were children under 12 years of age. The mortality in Henzada district (1·18) was again very high, but this and Hanthawaddy (1·17) and Rangoon (1·13) were the only instances in which the small-pox death-rate reached 1 per 1,000. In the three districts of the Arakan division no deaths were recorded from this disease ; the districts of Mergui and Prome were also exempt, and Amherst and Tavoy had only one death each. Unprotected cooly immigrants from India are, it is stated, a very prolific field for the propagation of this disease, and proposals for remedying the evil were under consideration.

Deaths ascribed to fever rose from 48,049 or 10·64 per 1,000 in 1895 to 51,521 or 11·41, a higher number than had been recorded in any previous year. By districts the death-rate was again highest in Akyab (20·51), Sandoway (15·65), Tharawaddy (15·45), and Prome (14·30). In three other districts the provincial rate was exceeded, and in the remainder the rates ranged from 11·39 to 5·01. The town death-rate from fever was 8·39 and the rural rate 11·87, as compared with 7·57 and 11·08 in 1895.

The deaths registered under dysentery and diarrhœa during the year aggregated 7,777, giving a death-rate of 1·72 per 1,000, against 8,794 or 1·95 in 1895. The highest mortality under this head was recorded by Tavoy, viz., 4·84, followed by Bassein 3·81, Myaungmya 3·58, and Rangoon 3·02 ; in the remaining 14 districts the death-rates ranged from 2·18 to 0·63. Speaking of the difference in the town death-rates from these complaints, ranging from 7·44 to 0·08, Dr. Sinclair remarks :—" Some of these towns get " their water supply from rivers, some partly from rivers and partly from wells, and some " have to rely on wells entirely. No relation between these various sources of supply " and the incidence of bowel complaints is discernible, nor can any be traced in the " sanitary defects or meteorology."

Some slight progress was made in the registration of vital statistics in Assam during 1896. The returns, however, are still far short of the truth. The total number of births registered during the year was 169,172, giving a ratio of 33·69 per 1,000 population, as compared with 155,631 or 31·00 in 1895. The highest birth-rate was again recorded by Goalpara district, viz., 42·71, and the next highest rates were 33·18 and 38·02 respectively Assam.

registered in the Cachar and Sylhet districts, these being the only three instances in which the provincial rate was exceeded, as the rates of the remaining districts ranged from 32·06 in Lakhimpur to 24·57 in Nowgong.

The deaths registered during 1896 aggregated 182,417, exceeding the births by 13,245 and the mortality of 1895 by 13,113. The death-rate was 36·33 per 1,000 of population, as compared with 33·72 in 1895. In the Surma Valley, comprising the districts of Cachar and Sylhet, the average mortality rose from 32·37 in 1895 to 35·43. The increase, however, was entirely in Sylhet, the death-rate in Cachar having fallen from 32·01 to 30·72. In the Brahmaputra Valley the average death-rate was 37·39, as compared with 35·33 in the previous year. Of the six districts in this division Nowgong recorded the highest mortality of 45·70 per 1,000, followed by Goalpara with 42·11, the ratios of the remaining four districts ranging from 40·52 to 29·39.

Cholera was somewhat less fatal than in 1895, the number of deaths having fallen from 18,962 or 3·78 per 1,000 to 17,042 or 3·39. The disease prevailed throughout the year and visited every district. Some of the districts recorded a very high cholera death-rate, notably Nowgong in the Brahmaputra Valley (4·22), which recorded the lowest mortality in 1895 (0·91). In the Surma Valley districts of Cachar and Sylhet the rates were respectively 2·96 and 3·86, both being higher than the rates of the previous year. The average death-rate from cholera in the towns was 5·50 per 1,000, nearly double that among the rural population. In some of them this ratio was greatly exceeded, especially by the Sadr towns of Tezpur, Dhubri, and Silchar, which registered cholera death-rates of 26·18, 22·38, and 14·09 respectively.

Cholera was very prevalent among tea-garden coolies who travelled up the Brahmaputra and Surma rivers in the early parts of the year, and 302 deaths from the disease occurred among the coolies who were landed during the year at the depots at Silchar, Dhubri, Gauhati, and Tezpur. Some of the civil surgeons, it is stated, are inclined to attribute the outbreaks of the disease in a large measure to the influx of tea-garden coolies, but the Chief Commissioner accepts the opinion, which has generally been held, that cholera is endemic in the province, and that its prevalence amongst the indigenous population is not due to any marked extent to importation from other provinces.

Small-pox was more prevalent than in the previous year, the deaths numbering 5,444 or 1·09 per 1,000, against 3,849 or 0·77. The highest rates were returned by Lakhimpur (4·16), Kamrup (2·91), and Sibsagar (2·24), all three showing a marked increase on the previous year's rates, which were 0·76, 1·11, and 0·08 respectively. In the Sadr and divisional towns, in most of which vaccination is compulsory, the small-pox death-rate fell from 5·35 to 1·27 per 1,000, the decrease being due chiefly to the great improvement in Barpeta, a town of about 12,000 inhabitants (where vaccination is not compulsory), which recorded 60 deaths or 5·05 per 1,000, against 433 or 36·43 in 1895. The disease was also severe in Lakhimpur town (4·82). Of the total small-pox deaths, 20 per cent. occurred among infants, and 53 per cent. among children between the ages of 1 and 12 years.

Over 55 per cent. of year's mortality were ascribed to fevers, including kala-azar. The number of deaths registered from them was 101,347, representing 20·18 per 1,000 of the population, against 92,359 or 18·39 in 1895. The increase occurred chiefly in Kamrup where the death-rate rose from 17·62 in 1895 to 25·88. But the highest fever death-rate was again recorded by Nowgong, viz., 36·31, followed by Goalpara 32·98, and Darrang 28·29. Of the 15,637 kala-azar deaths, 10,588 occurred in the Nowgong district, an increase of 257 on the number of the previous year. Owing to the high mortality from kala-azar in Nowgong, and its continued prevalence in other places, a specialist (Surgeon-Captain Rogers) was appointed to investigate and report on the disease. His report was under the consideration of the Chief Commissioner. The general conclusion come to by Dr. Rogers is that the disease is a very intense and epidemic form of malarial fever, and that it is communicable. He recommends the segregation and quarantine of infected persons and places, and the removal to new sites of houses in which cases of the disease have occurred.

Under dysentery and diarrhœa 16,004 deaths were registered, yielding a ratio of 3·19 per 1,000 of population, as compared with 15,523 or 3·09 in 1895. As usual, these diseases were most prevalent in Lakhimpur district, its death-rate under this head being 7·16. The next highest rates were 4·76 and 4·58 in the Cachar and Sibsagar districts. The provincial ratio was also exceeded in Sylhet district (3·45), and Khasi and Jaintia Hills district (3·97).

Madras.

The number of births registered during the year was 979,981 or 29·9 per 1,000, against 976,572 or 29·1 in 1895. The increase was spread over 12 of the 22 districts.

Excluding Madras town, which recorded a birth-rate of 41·5, Chingleput again registered the highest ratio of 39·5, and in ten other districts the rate was above 30 per 1,000, while in Malabar and Godavari the rates were only 22·5 and 25·8 respectively. Among the 57 municipalities, 17 recorded birth-rates over 40 per 1,000, in 31 the rates ranged between 30 and 40 per 1,000, and in seven others between 20 and 30. The mortality in 1896 exceeded that of the previous year by 17,068, the deaths having risen from 658,719 or 19·6 per 1,000 to 675,787 or 20·6. By districts the highest death-rate was, as usual, recorded in Madras, viz., 38·2: "a result which may be partly ascribed to the "greater accuracy of the returns, and partly to the insanitary condition of that city." In the other districts the mortality ratios ranged from 27·0 per 1,000 in the Nilgiris to 15·7 in Malabar. The average death-rate of the towns was 29·0 per 1,000, and that of rural areas 19·9.

Of the chief diseases, cholera was considerably more fatal than in 1895, the number of deaths having risen from 21,172 or 0·6 per 1,000 to 47,847 or 1·5. All the districts were affected, but the disease was most fatal in Bellary and Coimbatore, which recorded 4,205 and 10,731 cholera deaths respectively. The average death-rate in municipal and other towns from the disease was 2·3 per 1,000, against 0·8 in 1895, and that in rural tracts 1·4, against 0·6. Of the 57 municipalities, eight enjoyed immunity from the disease, while in 11 others the deaths did not exceed ten in each. On the other hand, some suffered very severely, notably Kilakarai in Madura with a cholera death-rate of 60·6, and Ambur in North Arcot with 23·4.

Small-pox deaths were reported from all the districts, and the total in the whole Presidency aggregated 9,410 or 0·3 per 1,000, against 5,111 or 0·1 in 1895. Of the districts, the disease was severe in those of Kurnool, North Arcot, and Ganjam, which recorded death-rates of 1·8, 1·2, and 1·2 respectively. In no other district did the mortality reach 1 per 1,000. Of the total 9,410 small-pox deaths 2,245 or 24 per cent. occurred amongst children under 1 year of age, and 3,632 or nearly 39 per cent. among those between 1 and 12 years of age.

From fevers the registered deaths showed a decrease of 16,568 on the previous year, the number having fallen from 277,337 or 8·3 to 260,769 or 7·97. The highest district rates were recorded in the Nilgiris (19·5), Kurnool (15·4), Vizagapatam (15·3); three other districts had ratios of over 10 per 1,000 and twelve over 5 per 1,000. Eight of the 57 municipal towns returned fever death-rates exceeding 10 per 1,000, the highest being 16·5 in Karur, followed by 13·8 in Tirupati and 13·6 in Madras. As compared with the previous year the fever death-rate of the town of Cuddapah fell from 18·3 to 10·2, which the Sanitary Commissioner (Dr. King) ascribed to the deficiency of the monsoon; while that of Karur rose from 10·6 to 16·5, which is attributed to the saturation of the subsoil of the town with soakage from cesspools.

The number of deaths registered under dysentery and diarrhœa in the Presidency was 24,802 or 0·76 per 1,000, an increase of 865 on the mortality of 1895. Of the districts, Madras came first with a death-rate from this cause of 5·3, against 4·9 in the previous year, followed by Chingleput, with 2·1 against 1·9. Regarding Chingleput, Dr. King writes: "This district is notorious for bowel affections. The increase may be due to a "better rainfall in certain parts of the district than it has had for some years past, "bringing about access of water to tanks from more than usually distant parts, and with it "filth, that would have been out of range of influence in ordinary years, or to fluctuation "of the subsoil water beyond normal limits." Of the towns, Coonoor recorded a death-rate under this head of 7·9 per 1,000, and Tanjore, Vizagapatam, Calicut, and Tuticorin of over 6 per 1,000 each.

Bombay.

The year 1896 in the Bombay Presidency was an unhealthy one. "In the early part "of the year," the Sanitary Commissioner (Surgeon Lieutenant-Colonel Clarkson) writes, "there was an outbreak of small-pox, chiefly in the Western and Gujarat Registration "Districts. Then cholera appeared in the Western, Central, and Southern Registration "Districts, and the mortality was largely in excess of last year. The outbreak was most "severe during July and August. Upon this, towards the middle of the rains, occurred "the outbreak of plague in Bombay City, and then, owing to the early cessation of the "rain, widespread scarcity necessitating the opening of famine works began."

In the Presidency, including Sind, 691,847 births were registered during the year, giving a birth-rate of 36·76 per 1,000 of population, as compared with 674,304 or 35·83 in 1895. Of the 24 collectorates and districts 16 recorded higher rates than in the previous year. Seven districts recorded birth-rates over 40 per 1,000, the highest being 47·55 in Ahmednagar, 47·30 in Khandesh, and 46·94 in Nasik. Hyderabad and Bombay City

returned the lowest rates, viz., 18·35 and 19·35 respectively. More children were registered as still-born in Bombay City than in any other district, and the percentage of still-born to born alive was 10·17. "I am still of opinion," the Sanitary Commissioner states, "that overcrowding on unhealthy areas and living in badly ventilated rooms are "the causes of this, to which may be added the kind of work women have to labour at."

The total number of deaths registered in the Presidency rose from 538,540 in 1895 to 596,472, and the rate per 1,000 of population from 28·61 to 31·69, which was made up of ratios ranging from 43·76 in Nasik to 17·46 in Hyderabad. The increase of 57,932 deaths was spread over all the districts except three—Ahmednagar, Sholapur, and Satara—and was common to all the specified causes of death. The excess was most marked in Broach and Kaira districts and Bombay City, the death-rates of which rose from 27·43, 26·93, and 30·58 respectively in 1895 to 39·98, 37·76, and 40·99. The month of greatest mortality was July, when 58,948 deaths were registered, and the last four months were the healthiest, notwithstanding that plague was in Bombay in the last quarter of the year.

Of the chief diseases, cholera caused 35,404 deaths, giving a ratio of 1·88 per 1,000, as compared with 8,890 or 0·47 in 1895. The province of Sind was practically free from cholera, only 5 deaths being reported from one district (Thar and Parkar) during the year. All the other districts were affected, though the epidemic was severe only in those of Bijapur, which returned a death-rate of 6·59 per 1,000, Poona 5·97, Ahmednagar 3·26, Belgaum 3·10, Satara 3·03, and Kolaba 2·08. Many of the towns, however, recorded much higher rates, especially Athni in Belgaum (13·05), Gogo in Ahmedabad (11·30), and Godhra in Panch Mahals (9·12). Deaths occurred in every month of the year, the months of greatest prevalence being April to September inclusive, the maximum of 9,772 being reached in July.

Small-pox deaths rose from 2,229 or 0·12 per 1,000 in 1895 to 6,443 or 0·34. Every district was affected, and all except four showed an increased mortality as compared with the previous year. In no district, however, did the death-rate reach 1 per 1,000, the highest rate recorded being 0·94 in Khandesh. According to age, 29·50 per cent. of the small-pox deaths occurred among infants under one year of age, and 51·78 per cent. among children between the ages of 1 and 12.

The number of deaths registered in the Bombay Presidency as due to fevers was 412,229 or 21·90 per 1,000 of population, against 388,848 or 20·66 in 1895. The average rate of 21·90 was exceeded in 10 districts, among the highest being 33·23 in Broach, 30·33 in Nasik, 30·20 in Kaira, and 29·63 in Khandesh. The increase of 23,381 was shared in by 18 out of the 24 collectorates. In each of the first seven months of 1896, from January to July, the fever mortality was above that of the corresponding months of 1895, and in each of the last five months it was lower. Of the five registration districts in the Presidency, the Western, Gujarat, and Sind districts recorded a higher mortality than in 1895. In the Gujarat Registration District the excess mortality amounted to 20,876, the largest portion of which occurred in the first months of the year, while in the last three, "the recognised "months of malaria," the increase was slight. Regarding the increase in this district, the Deputy Sanitary Commissioner observes: "During the first nine months of the year "small-pox and cholera were prevalent throughout the district, and it is possible that "many deaths due to one or other of these diseases were entered as deaths from fever. "Moreover, there are many villages in which every death is returned as due to fever, and "consequently in such villages a large proportion of deaths must be wrongly entered. It "is worthy of note that during the last three months of the year, when malarial fever is "most prevalent, the returns for the two years, 1895 and 1896, correspond fairly "accurately, while the large divergence occurs in the latter part of the cold weather when "deaths from chest affections are most liable to occur, and in the hot weather and first "months of the monsoon when epidemic diseases are most prevalent."

The number of deaths ascribed to dysentery and diarrhœa aggregated 36,046 or 1·92 per 1,000 of population, against 35,348 or 1·88 in 1895. In 17 collectorates out of 24 the mortality was higher than in the previous year, the greatest increase being in Nasik, where the death-rate under this head rose from 3·64 to 4·73. Of the 7 collectorates showing a decrease, the most marked instance was Sholapur, where the rate of mortality fell from 4·34 to 2·36.

In the latter part of the year under notice plague was declared to exist in Bombay Presidency. The disease first appeared in Bombay City, and by the end of the year it had extended to several districts, and resulted, according to figures furnished by the Sanitary Commissioner, in 2,908 cases having been reported, of which 2,086 were fatal, giving a death-rate of 0·12 per 1,000 of the population. The vast majority of the deaths

(1,803) occurred in Bombay City. An interesting account of the progress of plague during the year, and of the measures taken to suppress it, will be found in the Abstracts of the Reports of the Sanitary Commissioners with the Governments of India and Bombay, pages 104–109 and 165–169 respectively.

Berar.

In spite of a very hot season, a deficient and unseasonable rainfall, and at the close of the year a rise of prices which was sufficient to cause distress to all the poorer classes, the health of the year 1896 in Berar shows a considerable improvement on the previous year. The total number of births registered in the course of 1896 was 109,013 or 38·3 per 1,000 of population, showing an increase of 3,061 or 1·1 on the previous year. But although there was a rise in the provincial birth-rate as compared with 1895, and a considerable improvement over 1894 (33·3), the rate of 1896 was still below the average for the last decennial period (40·7) and much less than the estimated birth-rate for India (48·8). In the six districts of the province the birth-rates ranged from 44·1 in Buldana to 31·8 in Wun, but all recorded a lower rate than in 1895, except Wun and Basim, where there was an increase of 6·4 per 1,000 in the former and of 7·2 in the latter.

The deaths fell from 141,937 or 49·9 per 1,000 in 1895 to 124,787 or 43·8. Although showing a decrease of 6·1 per 1,000, the rate of the year under notice was still considerably in excess of the average of the decade, and 5 per 1,000 above the mean of the preceding five years. The improvement occurred chiefly under fevers and dysentery and diarrhœa, together accounting for a decrease of 11,002 deaths. Wun district recorded the highest death-rate (50·5); Amraoti came next with 45·6; the former being in excess of the ratio of 1895, while the other district rates were lower, especially Buldana and Basim, where there was a falling off of 16·2 and 15·9 respectively. In towns, the average death-rate fell from 46·4 in 1895 to 44·0, which was made up of ratios ranging from 65·7 to 23·5. In 6 towns the mortality was excessive, varying between 65·7 and 50·3 per 1,000.

Cholera was again epidemic during the year, and was the cause of 12,264 deaths or 4·3 per 1,000 of population, against 11,919 or 4·2 in 1895. The disease affected every district, and prevailed throughout each month of the year. According to districts, the highest death-rate was again recorded in Basim, where there were 2,891 cholera deaths, equal to a ratio of 7·3 per 1,000, against 3,976 or 10·0 in 1895. Wun came next with a death-rate of 6·9. The mortality from cholera was more than double that of the decade, and has only been exceeded four times in 26 years. The average urban and rural death-rates from cholera were 5·3 and 4·2 per 1,000 respectively. Of the 37 towns only five escaped the disease, and in 21 of these the death-rates exceeded the average for the province. Out of a total of 5,658 villages cholera prevailed in 704 or 12·4 per cent., as against 611 in 1895.

From small-pox, 810 deaths were registered, giving a ratio of 0·3 per 1,000 of population, as compared with 566 or 0·2 in 1895. More than half the deaths (415) were registered in Amraoti district, and the fewest (12) in the Basim district. Although the disease was present in many circles, it attained serious proportions in very few. Of the total small-pox deaths, 257 occurred in the towns and 553 in rural circles. Sixty-nine per cent. of the deaths occurred amongst children under 12 years of age, 162 or 20 per cent. being infants under one year. It is reported that the returns of Amraoti district were "swelled by cases of influenza under the name of *Kapsi matha*, which means "'cotton-pox,' the natives apparently connecting the disease with the unusually abundant "crop of cotton."

Under fevers, a mortality of 61,931 or 21·8 per 1,000 was registered, against 66,203 or 23·2 in 1895. By districts the death-rates from fever varied between 33·8 in Wun and 16·1 in Buldana. For the first five months of the year the fever mortality was unusually high, and was attributed to influenza.

The number of deaths attributed to dysentery and diarrhœa was 17,722 or 6·2 per 1,000, which was less by 6,730 or 2·4 than the number recorded in 1895. Ellichpur district, as usual, recorded the highest mortality under this head, viz., 10·3, against 13·8 in the previous year. Akola followed with 8·0, which was lower than the ratio (10·3) of the preceding year. The other district rates ranged from 6·7 in Amraoti to 2·7 in Wun.

IV.—JAILS.

Sickness and mortality in 1896.

There was less sickness among the jail population of India during 1896, as compared with the previous year, but a slightly higher mortality. The daily average sick per 1,000 of average strength fell from 42·95 in 1895 to 39·54, and the ratio of admissions into hospital from 1,006 to 939 ; while the death-rate rose from 26·59 to 27·79. There was no material increase in mortality, except in the Central Provinces, where the jail death-rate rose from 55·96 in 1895 to 72·11 in 1896. From cholera there were 142 deaths, as compared with 93 in 1895. In the jails of the Punjab, Assam, and Coorg, there were no deaths from this disease. There were more deaths from fevers, and dysentery and diarrhœa.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the several provinces for 1896, as compared with the previous year.

Provinces.	1896.			1895.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,154	39	28·78	1,247	42	27·47
North Western Provinces and Oudh.	897	51	28·83	902	58	27·45

India	939	40	27·79	1,006	43	26·59

Bengal.

The sanitary history of the Bengal jails for 1896 is not quite so satisfactory as that of the previous year. The year's statistics show that there was less sickness among the jail population of the province, with an increased mortality. The admissions into hospital were in the ratio of 1,154 per 1,000 of average strength, against 1,247 in 1895, the average daily sick-rate was 39 or 3 per 1,000 less, and the death-rate rose from 27·47 to 28·8. Among all classes of prisoners there were 501 deaths, and of these 461 were convicts. The diseases which contributed largely to the convict death-rate (29·0) were dysentery and diarrhœa 134 deaths, respiratory diseases 53, and cholera 60. In the previous year there were only 26 deaths from cholera amongst the convicts. The only serious outbreaks of the disease occurred in the Darbhanga and Bankipur jails, where the deaths from the disease numbered 22 and 12 respectively. Of the convicts who died in jail nearly 28 per cent. were admitted in good health, nearly 37 per cent. in indifferent health, and 35½ per cent. in bad health. Out of 47 jails the average death-rate among convicts was exceeded in 22, the highest being 168·0 in Daltonganj against 51·5 in the previous year, Darbhanga 106·4 against 25·8, Dinajpur 99·4 against 147·8, Barasat 96·8 against 77·6, and Bankipur 87·2 against 22·6. In nine others the mortality ranged from 78·1 to 50·7 per 1,000, and in four more over 40 per 1,000. In four jails there were no deaths. The high mortality of the Daltonganj jail was due to the bad state of health of the prisoners admitted, who had been exposed to privation and were suffering severely from malarial cachexia, four of the eight deaths having occurred within 20 days of admission to jail. The high death-rates at Darbhanga and Bankipur were due to the outbreaks of cholera already mentioned. Excluding the mortality from this disease, the death-rates were 25·7 and 39·6 respectively. At Dinajpur the high mortality was due to the wretched condition of health in which a great number of prisoners were admitted to jail, and at Baraset, which is one of the most malarious sub-divisions of Bengal, the prisoners confined there suffer much from fever. Sanitary improvements continued to be

made in most of the jails, and for the most part consisted in the provision of better ventilation, the substitution of a better class of latrine, and the substitution of lime-washing for the primitive method of cow-dung washing.

North-Western Provinces and Oudh.

The year 1896 in the North-Western Provinces and Oudh was one of much scarcity among the free population, and many of the admissions into the jails were in the last stages of want and emaciation. "The general population," the Inspector General observes, "was below par, and, I think, we may congratulate ourselves on the very small "death-rate and absence of any large epidemics. . . . I venture to say, that no body "of men could possibly pay more attention to the welfare of their prisoners, from a medical "point of view, than the Superintendents of all the jails in these provinces. They one "and all devote their attention most carefully to the health of the prisoners, taking "just as much interest in them as they do in the dispensary cases, and if mortality goes up, "it is due in, I may say, all cases to extraneous causes quite beyond their control." The admissions into hospital fell from 902 per 1,000 of average strength in 1895 to 897, the daily average sick from 58 to 51 per 1,000, while the death-rate rose from 27·45 to 28·83, which is considered to be low, and "shows that every attention was paid to "preserving the health of the prisoners." The mortality would, however, probably have been normal, but for the admission of enfeebled persons in an indifferent state of health. Of the 56 jails in the province, nine recorded a death-rate of over 50 per 1,000, the highest being 105·74 in Chunar temporary jail. Several of the jails showed a distinct improvement in health, chief among them being Moradabad, where, notwithstanding an epidemic of fever which necessitated the temporary evacuation of the jail for two months, the death-rate declined from 137·15 in 1895 to 41·15. The decrease in the death-rate of the unhealthy jail of Banda from 86·14 to 61·60 is also satisfactory. Of the causes of death, cholera in an epidemic form was again fortunately absent, only 14 deaths from the disease having been recorded in 1896, against 9 in the previous year, in all the jails. The mortality from dysentery and diarrhœa was somewhat less. Of the total 951 deaths in the jails 906 were of convicts, the death-rate being 29·43. According to length of residence in jail, the highest mortality occurred among convicts of from one to three years' standing, viz., 35·41, while among those during the first six months of imprisonment the death-rate was 32·71, against 35·26 in 1895.

Punjab.

The year 1896 was a healthy one in the Punjab, and there was less sickness in the jails than in the previous year, and the mortality was lower than in any year except 1868, when it was only 12·9. The admissions to hospital per 1,000 of average strength fell from 1,451 to 1,237, the daily sick-rate from 35 to 31, and the death-rate from 21·81 to 15·68, which is less than half the mortality of the province. "The steady decline during the past five "years in the jail ratios of admissions to hospital, of daily average sick, and of deaths "shows," the Government observe, "that really good work, with increasingly good results, "has been done by the medical officers in charge of jails." The highest death-rate was again returned by the Lahore Female Jail, viz., 50·96, the result of 8 deaths. In five jails there were no deaths, and in 12 the mortality was below 14 per 1,000. In several other jails the death-rates were below the provincial average. Of the total 186 deaths, all but ten were of convicts, giving a death-rate of 16·09. The mortality from dysentery and diarrhœa and from respiratory diseases, the chief causes of death, was lower than it had been at any time during the past 20 years. In 20 jails not a single death from dysentery and diarrhœa was recorded during the year.

Of the 176 deaths among convicts, 65 had not been more than six months in jail, but the highest rate, according to length of residence, was among convicts who had passed above seven years in jail (33·82 per 1,000), though, to some extent, this is accounted for by the 7 deaths being calculated on the small number of 207.

Burma.

The health of the jail population of Burma during 1896 was, on the whole, again satisfactory, and the death-rate was very low though slightly above that of the previous year. Among all classes of prisoners the admissions into hospital were in the ratio of 759 per 1,000, against 892 in 1895, the daily sick-rate was 35 or 3 per 1,000 less, and the death-rate was only 18·19, as compared with 17·93. It will also be observed that the Burma Jail death-rate for 1896 was the lowest of all jails except that of the Punjab, which was 15·68. As was observed last year, apparently no special measures were taken to obtain this satisfactory result, and it must be concluded that the low rate of mortality was in consequence of an intelligent and strict attention to all the ordinary details of jail management. To some extent the greater healthiness of prisoners in this province is accounted for by the people being "on the whole, more healthy and better nourished than

" those in some of the provinces of India." Of the 263 deaths which occurred during the year, 249 were of convicts, the death-rate being 17·75. Cholera was responsible for only 8 deaths, distributed over five jails. Among other diseases, tubercle of the lungs, &c., contributed 63 deaths, dysentery 41, and malarial fevers 14. The jails of the province continued to enjoy complete immunity from small-pox. Six of the jails recorded a higher death-rate than the average, the highest being registered by Bhamo, 108·43 per 1,000; followed by Pagan, 83·33; Mergui, 48·78; and Moulmein, 35·62; but the number of prisoners in these jails, except Moulmein, is small, and a few deaths give a high rate. It is reported that about half the jails in the province were in a chronic condition of overcrowding throughout the year, and that only five were not at one time or another in this state.

Central Provinces. The vital statistics of the jails of the Central Provinces for 1896 are extremely unsatisfactory. The admissions into hospital per 1,000 of average strength rose from 922 in 1895 to 1,108, the daily average sick-rate from 35 to 40 per 1,000, and the death-rate from 55·96 to 72·11, the highest mortality since 1887. These unfavourable results were in great part due to the condition of the new admissions, many of them being in a state of extreme emaciation indicating the effects of prolonged privation and want, and were admitted at once into hospital or the infirm gang. Out of the total number of 404 deaths, more than half (215) were caused by dysentery and diarrhœa, chiefly by a highly fatal and malignant form of the former disease. Six of the nineteen jails recorded a higher mortality as compared with the previous year. Those of Balaghat, Damoh, Narsinghpur, Seoni, Bilaspur, Mandla, and Saugor furnished the highest figures, their ratios ranging from 480·0 to 100·7 per 1,000. Among other diseases, respiratory diseases caused 43 deaths, fevers 11, and cholera 17. In the previous year there were 15 fatal cases of cholera. All but 20 of the 404 deaths occurred amongst convicts, the death-rate being 73·90, against 57·65 in 1895.

Assam. The health of the prison population of Assam in 1896 was better than in 1895. The rate of admissions to hospital declined from 1,287 per 1,000 to 1,128, the daily sick-rate from 58 to 51, and the death-rate from 59·21 to 50·86. The cause of the high mortality in 1895 was specially inquired into by the Chief Commissioner, who came to the conclusion that it was due chiefly to insufficient clothing, and to the absence of proper supervision over convicts employed extra-murally. Orders were issued for placing the whole system of extra-mural labour on a more satisfactory footing, and for the supply of dry and adequate clothing. These orders took effect from the 1st June 1896, and as a result the mortality of the latter half of the year was much lower than would appear from the figures for the year taken as a whole, and a further marked improvement is expected in 1897. Of the total 78 deaths among all classes of prisoners, 25 were due to dysentery and diarrhœa, and 11 to malarial fevers. There were only two deaths from cholera. All but four of the total deaths occurred amongst convicts, the death-rate being 52·46 against 61·68 in 1895. Excluding the lock-ups, the average death-rate of the nine jails in the province was 57·17 per 1,000, as compared with 69·02. Of these nine jails, five returned a higher mortality than in 1895, viz., Sibsagar 92·10 against 33·60, Nowgong 80·63 against 46·33, Gauhati 77·78 against 56·91, Silchar 61·99 against 31·44, and Shillong 58·74 against 45·67. There was ample accommodation as a whole for all the prisoners, and although there was at times overcrowding in some prisons, it was remedied by transferring excess prisoners to other jails.

Madras. There was less sickness among the prisoners in the Madras Presidency in 1896 than in the previous year, but the mortality was slightly higher. The hospital admission rate fell from 643 per 1,000 of average strength to 583, the daily sick-rate was 25, or 1 per 1,000 less, while the death-rate rose from 18·18 to 19·51, but with this exception it was lower than that of any previous year since 1886. The average death-rate of the central jails was again satisfactory, 17·8 per 1,000. The Criminal Leper Ward recorded a death-rate of 71·74, being the result of one death among an average strength of 14, but the most unhealthy jail was Parvatipuram, which recorded a death-rate of 96·06 per 1,000. Owing to the persistent unhealthiness of this jail it was closed during the year, as was also the Cuddapah Jail for the same cause. Rajahmandry Jail returned the next highest death-rate (47·09), resulting from 40 deaths among an average strength of 849. The high mortality in this jail is said to have been due partly to carelessness in the selection of prisoners for particular kinds of labour, and probably also to the want of proper supervision. The matter was being inquired into. Of the remaining 21 jails, the mortality ranged from 33·81 to 12·17 in 16, while in eight

there were no deaths. Dysentery and diarrhœa and respiratory diseases were the chief causes of mortality among the prisoners, the death-rate from the former being 4·90 per 1,000, and from the latter 2·58. From cholera there were only two deaths, one in Pallamcottah Jail and one in Berhampur. Of the total 187 deaths convicts contributed 168, representing a ratio of 20·33 per 1,000 of average strength, as compared with 19·26 in 1895.

Bombay.

The general health of the prison population of the Bombay Presidency during 1896 was less satisfactory than in the previous year. The rate of admissions to hospital per 1,000 of average strength fell from 956 to 861. The daily sick-rate (32) was 2 per 1,000 more, while the death-rate rose from 29·23 to 31·89 per 1,000. Among the convicts the mortality was 33·4 or 1 per 1,000 more than in 1895. Seven out of the 18 jails were overcrowded throughout the year, and of these seven three, the Common Prison, Bombay, and the jails of Shikarpur and Thana, recorded convict death-rates of 42·6, 71·0, and 113·6 per 1,000 respectively. The only other jails which recorded a mortality above the average were the Sind Gang 35·5 and the Deccan Gang 33·7. All but 26 of the total 263 deaths (including 18 in the lock-ups) occurred among the convicts. The chief causes of mortality were—dysentery and diarrhœa 42 deaths, respiratory diseases 66, including 52 from pneumonia, fevers 14, anæmia and general debility 7, and cholera 29. Of the cholera deaths 23 occurred in the Thana jail and formed a third of its mortality. The epidemic broke out in July and continued into the following month. The first two cases occurred among prisoners employed on grinding grain and on cane work. The disease afterwards spread to all parts of the prison. "All possible measures calculated to check and exterminate "the epidemic were adopted, and within just four weeks from the date of the first case the "final seizure was recorded." The cause of the outbreak could not be clearly traced, but the disease is supposed to have been introduced by warders or convicts, cholera having been very prevalent in the district prior to its appearance in the prison. Pneumonia, as usual, was very prevalent in the Sind jails, 94 cases, out of a total of 188, having occurred in them, and 32 of the 52 deaths. Shikarpur was the chief sufferer, with 40 cases and 21 deaths.

Berar.

The vital statistics of the jails in Berar show that the general health of the prisoners in 1896 continued to be satisfactory. The rate of admissions into hospital per 1,000 of average strength declined from 877 to 594; the daily sick-rate also fell from 23 to 18, while the death-rate rose from 23·26 to 25·13. The year was a very healthy one in all districts except Wun, and there were no circumstances connected with the health of the prisoners calling for special notice. There was a marked improvement in the health of the prisoners at Akola, though the mortality (25·72) is still considered to be higher than it ought to be, without any special cause to account for it. Apparently it is influenced by advanced age, for 9 out of the 14 deaths were men of over 55 years of age, the majority being too old and decrepit to battle against illness. The highest mortality was recorded in the Yeotmal Jail, where there were seven deaths among an average strength of 97, giving a death-rate of 71·92. All but three of the 36 deaths occurred amongst convicts, their death-rate being 23·81 per 1,000, as compared with 25·64 in 1895.

V.—VACCINATION.

General results. During 1896-97 there were 7,309,087 persons successfully vaccinated in the several provinces of India, being an increase of 85,496 on the number of the previous year. According to age, over $2\frac{3}{4}$ millions (2,892,039) of the total were children under one year of age, and nearly $3\frac{1}{4}$ millions (3,234,392) were children between the ages of one and six years. The proportion of population protected against small-pox by the year's operations ranged from 55·45 in Coorg and 46·86 in Burma to 28·87 in the North-Western Provinces and Oudh. In the vaccination of infants the best results were, as usual, obtained in Berar, Bombay, and the Punjab, where 66·8, 59·1 and 58·5 per cent. respectively of the children born during the year (estimated at 40 per 1,000 of population) were protected against small-pox. In the Central Provinces the percentage was 47·5, and in the remainder it ranged from 30·9 in Burma and 30·7 in the North-Western Provinces and Oudh to 17·6 in Bengal.

Statement showing the total number of persons successfully vaccinated during the year 1896-97 :—

Province	Population among whom Vaccination was carried on (Census of 1891).	Number of Persons successfully vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Children born during the Year (calculated at 40 per 1,000 of Population) successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	71,053,516	2,213,915	29·62	498,979	1,413,785	17·6
North-Western Provinces and Oudh.	47,146,033	1,362,169	28·87	578,390	566,881	30·7
Punjab	20,724,940	764,466	36·65	485,204	129,549	58·5
Central Provinces	12,228,229	388,689	30·56	232,124	93,667	47·5
Berar	2,897,040	99,991	34·5	77,490	15,647	66·8
Burma	8,146,855	381,797	46·86	105,213	177,009	30·9
Assam	5,644,258	251,568	43·31	45,865	145,955	20·4
Madras Presidency	35,651,577	1,118,203	31·1	330,819	559,657	23·2
Bombay Presidency	22,701,942	718,474	35·34	536 666	128,129	59·1
Coorg	173,055	9,815	55·45	1,289	4,113	18·6
TOTAL	226,357,445	7,309,087	32·24	2,892,039	3,234,392	31·3

Bengal. The total number of vaccinations performed in Bengal during 1896–97 was 2,293,655, of which 2,213,915 were successful, against corresponding figures in 1895–96 of 2,277,081 and 2,200,472. The primary operations numbered 2,223,128, of which 98·50 per cent. were successful. According to age, 498,979 of the successful primary vaccinations were of children under one year of age, and 1,413,785 were between one and six years. For the whole province the successful vaccinations were in the proportion of 29·62 per 1,000 of the population. Estimating the births during the year at 40 per 1,000, the percentage of infants successfully vaccinated was only 17·6, a ratio far below that attained in other provinces. There was, however, an improvement of three per cent. in the protection afforded to infants as compared with the results of the previous year.

Three methods of vaccination are practised in the province—(1) with lymph taken direct from the calf; (2) with calf lymph prepared with lanoline; (3) with human lymph taken by arm to arm transfer. Dr. Dyson again expresses his belief in vaccination direct from the calf, which he is confident will soon entirely supersede the arm to arm method of vaccination which, he says, is objectionable to the people in Bengal.

He gives statistics showing that in many districts the operations performed direct from the calf increased very considerably as compared with the previous year, and remarks :—
"When I suggested vaccination direct from the calf in 1893, instead of the arm to arm "method, I was told that it was impossible in Bengal. I persevered, however, with the "idea, and the above figures show what has been done in the three years which have since "elapsed. I decline to believe that the system is impracticable in the districts which "show no work in this connection."

As regards the attitude of the people, Dr. Dyson stated in his last report that the people seemed to be gradually realising the benefits of vaccination, but that there were still places where vaccination was opposed chiefly on sentimental grounds.

North-Western Provinces and Oudh.

In spite of the prevailing scarcity during the year vaccination continued to make steady progress in the North-Western Provinces and Oudh. The total number of persons vaccinated rose from 1,499,253 in 1895–96 to 1,528,478 in 1896–97, and the successfully vaccinated from 1,343,207 to 1,362,169. The proportion of persons protected by vaccination is, however, still very small, the ratio for the year being only 28·87 per 1,000, which is the smallest ratio attained in any province in India. Primary vaccinations numbered 1,443,741, of which 94·65 per cent. were successful. Of the 1,309,717 successful primary cases, 578,390 were infants and 566,881 were children over one and under six years of age, the former showing a satisfactory improvement as compared with the number of the previous year, and the latter a decrease. Estimating the births at 40 per 1,000 of the population, 30·7 per cent. were successfully vaccinated during the year. But, including the figures for children between one and six years, which show that the arrears of unprotected children remaining at one year of age have been largely overtaken within the last five years, the successful primary vaccinations equalled 78·83 per cent. of the births.

In previous years the areas of operation had been divided for the purposes of control into three circles, each in charge of a Commissioned Medical Officer, acting as Superintendent of Vaccination and Deputy Sanitary Commissioner. From the 1st February 1896 the number of these officers has been reduced, and the areas of control have been re-arranged in two circles.

In the first circle, where in some districts vaccination for years past has been more fully established than elsewhere in the province, the average ratio of success of its 27 districts equalled 30·38 per 1,000 of the population, against a mean for the five previous years of 27·34. In the second circle, the average ratio of its 22 districts was 27·58 against a five years' mean of 20·97. The Vaccination Act is in force in all the municipalities, but in some places it is not worked as efficiently as it should be. The results, however, show a slight improvement on the previous year, the ratio of successful vaccinations per 1,000 of population of the municipalities having risen from 38·15 to 38·55.

Punjab.

The results of vaccination in the Punjab in 1896–97 are not, on the whole, so satisfactory as those for 1895–96. Altogether 902,435 operations were performed, showing a decrease of 18,762 cases as compared with the figures of the previous year. The decrease was almost entirely among primary cases, for the number of re-vaccinations (229,335) was less only by 96. Of the primary cases, 93·22 per cent. were successful. The number of successful cases among children under one year of age fell from 487,217 or 58·8 per cent. of the births, calculated at 40 per 1,900 of population, to 485,204 or 58·5 per cent. The provincial ratio of persons successfully vaccinated per 1,000 of the total population was 36·65, against 37·44 in the previous year. Animal lymph was chiefly used, and during the year over 80 per cent. of the vaccinations were performed with it. The diminution in the returns was in some measure due to a most severe and widespread epidemic of small-pox which visited the province during the year. It is noticed that although the mortality was much smaller in districts in which vaccination is more thoroughly carried on than in others, the high death-rate from this disease for the province (2·19) shows that a large number of persons are in an unprotected state.

Burma.

Considerable progress was made in vaccination work in Lower Burma during 1896-97. The total number of persons vaccinated was 292,892, as compared with 245,065 in the previous year. The increase of 47,827 was contributed by 17 of the 20 districts, but chiefly by Thaton and Henzada, where the excess amounted to 14,982 and 11,877 respectively. The percentage of success in primary operations continued to improve. Out of 268,881 primary cases, 92·01 per cent. were successful, against a corresponding ratio of 91·22 in the previous year. The number of infants protected was 63,918, equal to about 34 per cent. of the births, estimated at 40 per 1,000 of the population.

The Vaccination Act was extended to three more towns during the year. Its benefits are less appreciated in rural tracts, because its efficacy is not so well understood ; but the large increase in the number of operations within the last few years—the successful primary cases having nearly doubled—is a sign " that the popular distrust, such as it is, " is being gradually overcome."

In Upper Burma 130,356 vaccinations were performed during 1896–97, being an increase of 9,678 on the number of the previous year, the excess being spread over 15 of the 18 districts. The quality of the work also showed improvement, the percentage of success in primary vaccinations having risen from 92·63 in the previous year to 93·34. Estimating the births at 40 per 1,000 of population 29·6 per cent. were successfully vaccinated, practically the same as in 1894–95. In the province of Burma as a whole the ratio of successful vaccinations per 1,000 of population was 46·86, as compared with 39·39 in the previous year, and the percentage of infants successfully vaccinated, estimating the births at 40 per 1,000 of population, was 30·9 as compared with 22·0 per cent. in 1895–96.

Central Provinces. Vaccination work in the Central Provinces was considerably restricted during 1896–97 on account of (1) scarcity and widespread distress, (2) falling off in the number of births, and (3) emigration of the people from their villages while in search of employment or the means of subsistence. There were 413,809 persons vaccinated during 1896–97, showing a decrease of 51,666 on the number of the previous year. Primary vaccinations fell from 397,261 to 367,821. The percentage of success in primary cases was 96·20, against 96·22, and the proportion of the total population protected by vaccination was 30·56, as compared with 35·99 in 1895–96. Of the 18 districts in the province, ten showed a decrease in primary operations, and eight an increase. In the protection of infants there was a falling off of 7,741, the number vaccinated under one year of age during the year having decreased from 239,865 to 232,124.

Animal lymph appears to be becoming popular in these provinces, and there is now very little prejudice against it. The Sanitary Commissioner says: "Great progress has "been made in the matter of substituting animal for human lymph. In many districts "lanoline lymph is used effectively. Arm-to-arm vaccination is now practised in very "few places." With the lymph obtained from calves, 240,217 children were vaccinated during the year, and of this number 94 per cent. were successful.

Assam. The results of vaccination work in Assam for 1896–97 compare favourably with those for the previous year. There were 274,696 operations performed by all agencies in the province, which is an increase of 14,006 over the figures of 1895–96. All the plains districts contributed to the increase, but there was a falling off in several of the hill districts, especially in Kamrup (4,298). The largest increase occurred in Sibsagar district (7,971), followed by Sylhet (5,354). Of the total operations 267,171 were primary cases, and of these 96·6 per cent. were successful. The Compulsory Vaccination Act was in force during the year in ten places, their population being 66,313. The number of infants successfully vaccinated was 45,865, representing only 20·4 per cent. of the births, estimated at 40 per 1,000 of the population.

Madras. The aggregate number of vaccinations performed in the Madras Presidency during 1896–97 was 1,247,720, being an increase of 49,549 on the operations of the previous year. Of the total, 1,173,121 were primary cases, of which 92·5 per cent. were successful, against 91·22 per cent. in 1895–96. The number of children under one year of age successfully vaccinated rose from 314,117 to 330,819, which represented only 23·2 per cent. of the estimated births, as compared with 22·0 per cent. in the previous year. Vaccination is compulsory in all municipalities, except the newly constituted municipality of Tiruvannamalai, and the number of operations performed by municipal vaccinators fell from 120,190 to 118,655. In the town of Madras the number of operations performed was 27,021, or three less than in the previous year. Of the 21 districts there was an increase of work in 13, the most marked case being that of Vizagapatam (22,844); this improvement is the more satisfactory as in the previous year Vizagapatam showed the largest falling off (12,207). Animal vaccine was employed both in districts and municipalities, and the total number of vaccinations performed with it was 1,241,843, or only 5,877 less than the total number of operations, and of these 1,113,050 or 89·4 per cent. were successful, the corresponding figures for the previous year being 1,190,541, 1,074,919, and 92·3 respectively. The best results were obtained, as usual, from calf-to-arm vaccination, with a percentage of success of 94·7.

Bombay. Omitting the statistics of five Native States which are not under the supervision of the Bombay Vaccination Department, the out-turn of vaccination work in the Presidency fell from 810,804 operations in 1895–96 to 810,723. This shows a decrease of 81. The total primary cases rose from 732,648 to 736,511; the percentages of success being respectively

93·23 and 93·69. The substitution of animal for human lymph continued to increase in the Presidency. In the City of Bombay vaccination with animal lymph exclusively was carried on throughout the year. Of the 680,033 primary successful cases, nearly 80 per cent. were infants under one year of age. Reckoning the births at 40 per 1,000 of population, 59 per cent. were protected from small-pox. Inoculation was not practised anywhere in the Presidency during the year, and no instances were reported of any disease having been communicated through vaccination.

Berar.

There was an improvement in the out-turn of vaccination work in Berar during 1896-97, the total operations having risen from 106,605 in 1895–96 to 120,111, an increase of 12·6 per cent. The number of primary vaccinations was 98,594, out of which 96·81 per cent. were successful, against 92,694 and a rate of success of 95·94 in 1895–96. Of the total number of successful primary operations, 77,490 were performed on infants under one year of age ; estimating the births at 40 per 1,000 of population, 66·8 per cent. were protected from small-pox. The Sanitary Commissioner continues his statement showing the efficacy of vaccination in checking small-pox mortality in Berar ; the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of five years 1868-69 to 1872–73, to 35·8, the mean of five years ending 1892–93 ; the mortality from small-pox for the same periods has declined from 2·02 to 0·2 per 1,000. The corresponding ratios for 1893–94 were 35·0 and 0·06 per 1,000, those for 1894–95 were 32·2 and 0·37, for 1895–96 the ratios were 31·8 and 0·2, and for 1896–97 34·5 and 0·2 respectively. The Vaccination Act is now in force in all the municipal towns, the Act having been extended to Karinja during the year. It is reported to have worked satisfactorily in all municipal areas.

With regard to the lymph in use in the province, Dr. Little says : " Since I first " entered upon the duties of the Sanitary Commissioner's office in October 1878, animal " lymph obtained from the cow has been more or less used in the province. It was first " tried for the purpose of renewing our supply and starting the season's operations, and " we were thus able to dispense with the annual supplies of English lymph furnished by " Government for this purpose. After a time, when Superintendents and Vaccinators " became more skilled and experienced in animal vaccination, the work of the province " came to be carried on partly with animal and partly with humanized lymph until 1890, " when a scare was raised as to the possibility of transmitting leprosy through the " medium of humanized lymph. Arm-to-arm vaccination was then completely abandoned, " and the work carried on entirely with lymph propagated from the cow or buffalo. The " people of the province were by this time quite accustomed to the idea of cow vaccination which had been thus gradually and quietly introduced, and there was no difficulty " experienced in substituting animal for humanized lymph ; indeed, native feeling had " come to prefer the animal lymph, for they were quick to perceive that their children " suffered less when cow lymph was used ; that it either took or failed without subsequent " ulceration, whereas the arm-to-arm method in the hands of a careless vaccinator not " infrequently resulted in severe ulceration and inflammation of the child's arm. Over " and over again have the villagers told me this, and personally I seldom or ever see now " the ulcerated and inflamed arms which were but too common under the old arm-to-arm " system as practised by uneducated and unprofessional men at a distance from immediate " supervision."

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries open in the several provinces of India during 1896 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1896	455	47,109	2,637,501	2,684,610
	1895	427	45,243	2,434,536	2,479,779
Calcutta and Howrah	1896	16	25,647	258,794	284,441
	1895	12	26,879	266,672	293,551
North-Western Provinces and Oudh	1896	350	62,441	3,892,918	3,955,359
	1895	340	61,514	3,955,681	4,017,195
Punjab	1896	267	62,877	3,070,117	3,122,994
	1895	257	56,172	3,204,445	3,260,617
Burma	1896	96	30,929	677,560	708,489
	1895	93	30,607	602,380	632,987
Central Provinces	1896	95	13,527	1,360,602	1,374,129
	1895	117	12,224	1,249,366	1,261,590
Assam	1896	101	6,554	562,142	568,696
	1895	97	5,987	538,951	544,938
Coorg	1896	7	1,245	43,902	45,147
	1895	7	1,343	36,859	38,202
Madras	1896	489	56,625	4,189,762	4,246,387
	1895	498	55,767	3,977,114	4,032,881
Bombay	1896	325	47,090	2,373,637	2,420,727
	1895	317	47,686	2,442,330	2,490,016
Berar	1896	46	4,500	340,134	344,634
	1895	46	4,912	346,443	351,355
TOTAL	1896	2,247	348,544	19,407,069	19,755,613
	1895	2,211	348,334	19,054,777	19,403,111

Bengal.

There was again an increase in the number of charitable dispensaries in Bengal in 1896, and in the patients under treatment in them, as compared with the figures of the previous year. The total number of dispensaries at work during 1896 in Bengal, exclusive of the medical institutions at Calcutta, was 455, an increase of 28 on the number of the preceding year. At these there were 2,684,610 patients under treatment, 47,109 being in-door and 2,637,501 out-door patients, against 45,243 and 2,434,531 respectively in the previous year. This shows a total increase of 204,831, which was attributed partly to the opening of new dispensaries and partly to the increasing popularity of the institutions. These figures, however, fall short of those for the North-Western Provinces, Madras, and the Punjab, though Bengal has more dispensaries than any of the other provinces, except Madras. The Inspector-General remarks: "The annual reports of medical officers "for the year 1896 show that increased interest has been taken in dispensary manage- "ment, and that Managing Committees have very frequently endeavoured to carry out "suggestions for improvement made by civil surgeons and other inspecting officers. In "many cases new and suitable beds, clothing, furniture, with additional comforts and "conveniences have been provided for patients. New surgical equipment and appliances "have been furnished, and the dispensary buildings themselves have been put in good "order."

There was again a satisfactory increase in the number both of women and children. The increase among women, though not so great as in the previous year, amounted to 24,244, the number having risen from 398,994 to 423,238. Of the diseases under treatment at the dispensaries, cholera, dysentery, and malarial fevers were responsible, as usual, for the largest number of cases. From malarial fever the cases fell from 525,300 in 1895 to 506,757, equal to 18 per cent. of the total number of patients; next came dysentery with 64,641 cases, against 59,757 in 1895, and from cholera the number of patients rose from 11,497 to 14,388. Cases of venereal diseases rose from 57,008 to 64,218. Notwithstanding the increase in in-door patients the deaths fell from 5,568 or 123·1 per 1,000 of total treated in 1895 to 5,487 or 116·4 in 1896. Great attention is paid in these institutions to surgery, and during the year 122,643 operations were performed, against 120,084 in 1895, and of these 224 terminated fatally. The more important operations numbered 3,262, of which 2,567 were extractions of the lens.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1896 and the previous year :—

Name of Institutions.	1896.				1895.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.
Medical College Hospital	4,485	35,457	39,942	118·6	6,951	58,441	65,392	107·7

Total Calcutta Hospitals and Dispensaries	23,867	247,871	271,738	132·8	26,130	254,981	280,111	135·9
Howrah General Hospital	1,780	10,923	12,703	236·5	1,749	11,691	13,440	245·2
Grand Total	25,647	258,794	284,441	140·0	26,879	266,672	293,551	143·2

The figures for 1896 show a decrease of 7,878 in out-door patients, and of 1,232 in in-door patients, which is accounted for by the year being less unhealthy than the previous one. The death-rate for all the hospitals excluding the Eye Hospital was 142 per 1,000 of the number treated, against 143·2 in the previous year. Cholera patients rose from 600 to 1,007, and the fatal cases from 349 to 566. There was a great epidemic of small-pox in the previous year, when 771 cases were admitted to hospital, and 279 died, but in 1896 there were only 57 admissions of which 16 terminated fatally. Dysentery was not so prevalent, and the number of patients fell from 8,383 to 7,778. The number of cases of malarial fever also fell from 59,256 to 48,982. Venereal diseases show an increase of 542 patients, the number treated having risen from 13,674 in the previous year to 14,216. There were 24,067 surgical operations performed, exclusive of 6,340 of which no details were given, and of the total death ensued in 160 cases, against 124.

North-Western Provinces and Oudh.

During 1896 350 hospitals and dispensaries were at work in the North-Western Provinces and Oudh, or ten more than in the previous year. The number of patients who received medical aid was 3,955,359, against 4,017,195 in 1895. There was thus a decrease in 1896 of 61,836, which was "principally due to famine, on account of which the people "flocked to poor-houses and relief works; also to healthiness of the year, as indicated

" specially by the diminution of cases of malarial fever, and to the issue of a circular " which has stopped the practice of giving fresh tickets to those who have lost their " attendance tickets and thus re-entering them as *new* cases in the register." Of the total number 51·48 per cent. were men, 21·42 per cent. were women, and 27·10 per cent. were children, the two latter showing a small increase on the figures of the previous year, which were 20·88 and 26·84, respectively. The in-door patients numbered 62,441 as compared with 61,514 in 1895, and among them there were 3,704 deaths, giving a death-rate of 59·3 per 1,000, against 3,502 or 56·9 in the previous year. Of the diseases for which the patients were treated 580,752 were suffering from malarial fevers, a decrease of 102,384 on the number of 1895 ; cases of cholera rose from 2,743 to 4,190, and cases of diseases of the eye increased from 319,838 to 343,791. From venereal diseases there were 83,765 patients, against 78,640 in the previous year. The progress of surgical work kept pace with the general increase in the number of patients applying for relief. The number of surgical cases rose from 192,582 to 206,299. These included 31,114 major operations, of which 24,463 resulted in cure and 491 were fatal. Of the 31,114 major operations 9,538 were for cataract, of which 83 per cent. were successful, as compared with 10,565 operations and a percentage of success of 84 in 1895.

Punjab. Ten more dispensaries were at work in the Punjab during 1896 than in the previous year, bringing the total number of these institutions up to 267. At these, 3,122,994 patients were under treatment, being a decrease of 137,623 on the number of 1895. The decrease, however, was chiefly among out-patients. The year was much more healthy than the previous one, and this is the main cause of the smaller number ef applicants for advice and treatment. Of the diseases for which patients sought relief there were 870 cases of cholera, being an increase of 849 on 1895. Cases of malarial fever fell from 438,166 to 363,913. Diseases of the eye showed an increase of 24,215 cases, the number treated in 1896 being 380,034, against 355,819. From venereal diseases there were 34,414 cases under treatment, an increase of 578 on the previous year's figures. Among the in-patients there were 2,339 deaths during the year, being in the ratio of 44·2 per 1,000 of the number treated, against a death-rate of 43·3 in 1895. In surgical work operations decreased from 214,655 in 1895 to 193,370. Of these, 181,634 were cured and 309 died. The falling off in the number of operations is accounted for in some measure to the fact " that the year's " figures represent, as far as possible, the number of patients operated on, and not as " heretofore, merely the number of separate surgical measures employed simultaneously, " such for instance as the opening of several small abscesses in one person for the cure of " the same diseased state." There were 4,837 cases of extraction of the lens for cataract, including 141 remaining under treatment from the previous year ; of these 86·7 per cent. resulted in cure.

Burma. The number of dispensaries existing in Burma at the end of 1896 was 96, or three more than in the previous year. At these, 708,489 patients attended, as compared with 632,987 in 1895. In-door patients rose from 30,607 to 30,929, of whom 23,063 were cured, and 1,921 or 60 per 1,000 died, against 2,150 deaths or 90 per 1,000 in the previous year. The total number of Burmans treated was 412,411, equal to 58 per cent. of the total patients. Malarial fevers, as usual, headed the list of maladies under treatment, the number being 126,085, against 112,864 in the previous year. Cases of venereal disease rose from 24,960 in 1895 to 26,198. Surgical work also showed an increase of 466 operations, the number having risen from 14,271 to 14,737. The number of patients cured, after being subject to operation, was 14,012, and 66 died.

Central Provinces. The number of hospitals and dispensaries at work in the Central Provinces during 1896 was 95, or 22 less than in the previous year. The total number of patients rose from 1,261,590 to 1,374,129. The increase extended to both in and out door patients, the former having risen from 12,224 to 13,527, and the latter from 1,249,366 to 1,360,602. Among the in-patients there were 1,851 deaths, or 136·8 per 1,000 of total treated, an increase of 23 per 1,000 on the mortality of 1895. The increase in attendance, it is observed, would no doubt have been greater but for the establishment of poor-houses and relief works on account of the scarcity. These both furnished some medical relief of their own, and also took off a part of the demand on the regular dispensaries, which proceeds to a large extent from persons whose ailments are mainly due to want. As regards the different kinds of diseases treated the statistics do not exhibit many features that call for notice. Malarial fever, ulcers, diarrhœa, and diseases of the eye and skin were responsible, as usual, for the largest number of cases treated.

There were 23,176 surgical operations porformed, against 31,416 in 1895. Of these, 22,174 resulted in cure and 87 in death. In the operations for cataract there has been a considerable increase, viz., from 479 in 1893 and 949 in 1894 to 1,299 in 1895 and 1,508 in 1896.

Assam.

In the province of Assam there were 101 dispensaries open during 1896, or four more than in the previous year. At these, 568,696 patients were under treatment, against 544,938 in 1895. The in-patients numbered 6,554, as compared with 5,987, and of these 3,459 were discharged cured, 546 relieved, 1,139 discharged otherwise, and 993 died, the latter representing 151·5 per 1,000 of the total in-patients, against a ratio of 188·2 in 1895. The increase in the number of patients treated was attributed partly to the opening of new dispensaries and partly to the growing popularity of these institutions. There was again a small increase of 299 among the indigenous population who resorted to the dispensaries as in-door patients, the number having risen from 1,633 to 1,932. The progress made within the past decade in the extension of the system of bringing medical relief to the poor of Assam, by means of dispensaries, may be gathered from the fact that the number of these institutions has increased from 46 to 101, and the total number of patients from 149,051 to 568,696, or by more than 281 per cent. Of the total number of persons who received medical aid, malarial fever, including kala-azar, accounted for 124,878 cases, or nearly a fifth of the total treated; skin diseases 128,829, worms 84,917, dysentery and diarrhœa 29,900, and diseases of the digestive system 22,693. Cholera patients numbered 2,734, against 1,786 in 1895. Of surgical cases there were 13,080, of which 12,393 were cured and 17 were fatal.

Madras.

Exclusive of the hospitals in the Presidency town there were 475 dispensaries working in Madras at the close of 1896, or 11 less than in 1895. The results of the year were again satisfactory. There were 4,042,533 patients under treatment, as compared with 3,839,354 in 1895. There was thus an increase of 203,179. Of the 39,020 in-door patients, 23,752 were returned as having recovered fully under treatment, 8,359 as relieved, and 3,313 as otherwise discharged. The deaths numbered 2,513, representing a ratio of 64·4 per 1,000 of the total in-patients, against 58·9 in the previous year. Diseases of the eye, other diseases of the digestive system, skin diseases, ulcers, malarial fevers, and intestinal worms were the most common diseases under treatment during the year. Cholera existed in an epidemic form throughout the whole Presidency, and 10,776 cases were under treatment in the various hospitals and dispensaries. The surgical operations rose from 141,765 in 1895 to 143,750. Of these, 133,071 were cured and 217 terminated fatally.

The number of medical institutions in Madras town rose from 12 in 1895 to 14 in 1896, and the number of sick treated increased from 193,527 to 203,854. The increase of 10,327 was entirely among out-patients, as the number of in-patients was less by 260. Amongst them, 8,670 cases were recorded to have been cured or perfectly recovered, 4,123 were relieved, 2,966 discharged otherwise, and 923 or 52·4 per 1,000 died, against a rate of mortality in 1894 of 56·6. Of the several diseases for which the patients were treated, malarial fever, diseases of the digestive system and respiratory system were, as usual, the most common. From cholera there were only 63 cases, from dysentery and diarrhœa 6,083, and from venereal diseases 4,174, of which 1,347 were afforded in-door relief. The surgical work performed in 1896 compares favourably with that of the previous year, the operations having increased from 27,715 to 27,903. The results showed that 11,040 cases were cured, 4,359 relieved, and 189 were fatal.

At the Madras Voluntary Venereal Hospital, which is included in the above hospitals in the city, there were 636 patients treated during 1896, an increase of 67 on the number of the previous year. The Superintendent writes: "Patients very rarely seek admission "into hospital in the primary stage of the disease. They usually come in when the "disease is well advanced, and in the enormous majority of cases they leave the hospital "before completely cured. This last fact is due, of course, to the system on which the "hospital is worked being a voluntary one."

Bombay.

Excluding the 11 medical institutions in the city of Bombay, there were 314 hospitals and dispensaries working in the Presidency during 1896. At these, 2,319,346 patients were under treatment, of whom 30,857 were in-door and 2,288,489 out-door patients, against 30,848 and 2,351,221 respectively in 1895. Malarial fevers, as usual, constituted by far the largest number of cases (386,551, or nearly 17 per cent. of the total treated), still there was a decrease of 43,832 when compared with the figures of

the previous year. Next to fever, eye and skin diseases, and worms were the most common ailments. Small-pox and cholera cases were much more numerous, the former having risen from 195 in 1895 to 480, and the latter from 1,813 to 5,879 ; dysentery and diarrhœa cases were also more numerous ; and patients suffering from venereal affections fell from 33,581 in 1895 to 30,482 in 1896. Of the in-door patients 21,758 were cured, 2,784 relieved, 2,943 discharged otherwise, and 2,228 died, the ratio of deaths to total treated being 72 per 1,000, an increase of 15 per 1,000 on the ratio of the preceding year. The numbers of both major and minor operations performed during the year were much larger than in 1895. The total number of patients operated on was 110,994, as compared with 114,193 in 1895, and of these 97,500 were cured and 190 died.

The total number of patients treated at the 11 civil medical institutions working in the town of Bombay during 1896 showed a decrease of 6,566, the figures being 101,381, against 107,947 in the previous year. The in-patients decreased in number from 16,838 to 16,233, and of these 9,773 were cured, 2,789 relieved, 1,042 otherwise discharged, and 1,715 died, the deaths being in the ratio of 106 per 1,000 of the in-patients, against 95 per 1,000 in 1895. As usual, local injuries, malarious fevers, eye diseases, and skin diseases were responsible for the majority of the cases. Venereal diseases contributed 4,799 cases, against 5,251. Cholera cases rose from 2 to 6, and those of dysentery fell from 1,571 to 1,509, but cases of diarrhœa rose from 3,260 to 3,454. The total number of patients operated on was 39,646, and of these 37,555 were cured, 1,816 relieved, 55 discharged otherwise, and 145 died.

Berar. As in 1895 there were 46 medical institutions at work in Berar during 1896. Of these, eight are hospitals wholly maintained by the State. The total number of patients under treatment was 344,634, against 351,355 in 1895. The decrease of 6,721 patients was attributed to a more generally healthy year, as is borne out by the death-rate of the province. In-patients numbered 4,500, of whom 3,647 were cured, and 349 died, which gives a death-rate of 78 per 1,000, as compared with a mortality of 244 or 59 per 1,000 in 1895. Malarial fevers continued to head the list of diseases from which relief was sought, but the cases again fell from 81,683 in 1895 to 71,822 ; nearly a fourth of the total patients were treated under this head ; diseases of the eye and skin came next in order. Cholera cases fell from 3,573 in 1895 to 3,001 ; there was also a small falling off in the number of admissions from bowel affections. There was a decline in surgical work ; the total number of patients operated on being 11,412, against 12,827 in 1895. Of these, 11,000 were cured and 23 died.

The Dufferin Hospital for women and children at Amraoti, which was opened on the 15th February 1895, continued to work satisfactorily. The in door patients during the year numbered 128, and the out-door 5,806, against 96 and 6,215 in the previous year. The operations fell from 270 to 161.

Lunatic Asylums.

Bengal At the five asylums in Bengal (viz., Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,102 lunatics, including 181 fresh admissions and re-admissions, were under treatment in 1896, being a decrease of 5 on the number of the previous year. In the course of the year under notice 61 patients were discharged as cured, and 31 as improved or otherwise, and 90 died. Compared with the figures of 1895, the number discharged was less by 17, while the deaths increased by 15. At the end of the year there were 918 persons still under detention, or 3 less than at the close of 1895. The health of the inmates of the asylum was not so good as in the previous year, the average daily number of sick being 85, against 59 in 1895 ; but the number of admissions into hospital were fewer by 56. The mortality during the year was higher than in any of the preceding 10 years, the number of deaths having risen from 75 to 90 and the death-rate from 81·5 to 98·4 per 1,000 of average strength. Satisfactory progress appears to have been made in the working of dairy farms at the asylums. From Dullunda a profit of Rs. 646 was reported, and the Dacca Asylum, besides affording a sufficient supply of milk to its inmates, realized Rs. 520 from the sale of milk to the public. The dairy farm at Berhampore was opened in the latter part of the year, and is now reported to be working satisfactorily.

In the Bhowanipur Asylum, containing European and Eurasian patients only, the inmates during 1896 numbered 51, against 54 in the previous year. Of this number 32 were under detention at the beginning of the year, and 19 were subsequently

admitted. In the course of the year 6 patients were discharged cured, 1 was dispatched to Europe under the Merchant Shipping Act, 2 were transferred to the care of friends, 1 was despatched to Europe as still insane, and 5 died, leaving 36 under confinement at the close of the year. As regards the health of the patients during the year, there were only 9 admissions to hospital, and 5 deaths. The proportion of deaths to average strength was 150·9 per 1,000, against 106·2 in 1895.

North-Western Provinces and Oudh.

The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the North-Western Provinces and Oudh in 1896 were 1,322, including 277 admissions during the year, against 1,289 in 1895. Before the close of the year 167 patients were discharged, of whom 132 were reported as cured, 35 were made over to friends, and 59 died, leaving 1,096 under treatment at the end of the year. The health of the asylum population was much better than in the preceding year, and the death-rate per 1,000 of average strength fell from 79 to 54·5. Dairy farming was again very successful at Bareilly. This farm was started towards the close of 1890, with a view to reducing the danger of enteric fever and cholera among British troops, by enabling them to obtain a purer supply of dairy produce. Besides giving employment to the inmates of the asylum, it has been of great use to the garrison and Civil Station of Bareilly. Schemes were under consideration for connecting the Benares and Agra Asylums with the municipal water-supply system.

Punjab.

The total number of lunatics in the Lahore and Delhi lunatic asylums in the Punjab during 1896 was 495, including 150 fresh admissions, against 478 in 1895. At the end of the year the number was reduced to 364 by the discharge of 109 patients (50 as cured, 37 made over to friends, and 22 otherwise discharged), and 22 deaths. The year being a fairly healthy one, there were fewer admissions into hospital, and the mortality was much lower in both asylums than in 1895. The total number of hospital cases was 408. In Lahore the cases fell from 492 in 1895 to 367, and the deaths from 40 or 168·0 per 1,000 of daily average strength to 18 or 76·6. Pneumonia was the cause of only 2 deaths in this asylum as compared with 14 in the previous year. In the Delhi Asylum the mortality was the lowest on record, the deaths numbering only 4 or 3·39 per 1,000, against 11 or 98·8 in 1895. Both asylums were again entirely free from cholera in 1896. The question of the construction of a Central Asylum for the province, to contain the patients of both the Lahore and Delhi Asylums, was still under the consideration of the Government.

Burma.

The Rangoon Asylum is the only one in the province of Burma. Until the year 1894 a number of lunatics were, for want of accommodation, confined and treated in the Rangoon central jail. The asylum has since been twice extended, and there is now accommodation for 414 insanes. During 1896 there were 442 patients in the Rangoon Asylum, including 92 fresh admissions, and the total was reduced at the close of the year to 319 by the discharge of 93 patients for different causes, and the death of 30. There was less sickness among them than in 1895, the admissions to hospital having fallen from 129 to 104. No epidemic disease occurred among the patients, and the deaths fell from 36 to 30, of which 10 were from tuberculosis, 3 from dysentery, 2 from chronic diarrhœa, and 5 from mania. Three of the deaths occurred within the first month, and 6 more within the sixth month of residence in the asylum, all of whom were civil lunatics. Of the 414 insanes 195 were criminal lunatics, and among them were 9 deaths as compared with 21 among civil lunatics, the excessive mortality among the latter being attributed to their wretched state of health on admission.

Central Provinces.

In the two asylums of the Central Provinces (Nagpur and Jubbulpore), there were 382 lunatics under treatment during 1896, or one in excess of the previous year, and of these 58 were fresh admissions. In the course of the year 43 patients were discharged as cured or otherwise, and 18 died, leaving 321 still under treatment at the commencement of 1897. The health of the patients was better than in 1895, and the admissions to hospital at Nagpur fell from 126 to 50, but at Jubbulpore they rose from 103 to 109. Cholera and small-pox were absent from both asylums. The chief cause of sickness was, as usual, malarial fever, from which there were 14 admissions at Nagpur, and 41 at Jubbulpore. At both asylums the mortality was lower as compared with the previous year. Of the total 18 deaths, Nagpur recorded 7, being in the ratio of 39·4 per 1,000 of average strength, against 12 or 70·2 in 1895. At Jubbulpore the number of deaths (11) was the same in both years, but the death-rate fell from 74·8 per 1,000 to 71·3. A dairy farm was started in 1895 at Nagpur Asylum with a fair amount of pecuniary success, for the

venture cleared its expenses, and in future, now that the initial expenses have been cleared, it may be expected to yield a considerable profit, besides affording healthy and congenial employment to some of the inmates of the asylum. The healthiness of the patients in this asylum is attributed to the liberal supply of milk from the dairy given to the inmates.

Assam. There is only one lunatic asylum in the province of Assam. This is situated in Tezpur, and the building is reported to be at present large enough for all demands on it. The total number of lunatics under treatment in the asylum during 1896 was 153, being an increase of nine on the number of the previous year. Of these, 42 were fresh admissions. At the close of the year the patients in the asylum were reduced to 126, 18 of the total number having been discharged, 7 died, and two escaped. Although the year was an unhealthy one in the district, there was less sickness in the asylum, and the mortality fell considerably. Of the 153 inmates 82 were admitted to hospital during the year, as compared with 23 in 1895. The number of deaths was the same in both years, and the death-rate was 60·1 per 1,000 of average strength in 1896, against 65·9 in 1895. Four of the deaths were from anæmia, and one each from dysentery, pneumonia, and tetanus.

Madras. At the commencement of 1896 there were 608 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 156 fresh cases were admitted, bringing the total population up to 764, or 50 less than the number in the preceding year. In the course of 1896 there were 134 cases of discharge, and of these 95 were cured. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. The health of the insanes was much better than in the previous year; the daily average sick fell from 123 to 87, and the deaths from 110 or 182·5 per 1,000 of average daily strength to 46 or 77·7. In all three asylums the mortality fell to about half what it was in 1895. There were no epidemics in any of the asylums, and only one imported case of cholera was treated in the Madras Asylum, while in the previous year there were 37 cholera deaths in this asylum. Of the total 46 deaths the Madras Asylum contributed 38, giving a death-rate of 89·6 per 1,000 on an average strength of 424, against a ratio of 213·6 in 1895. The death-rates of the other two asylums, Vizagapatam and Calicut, were 14·9 and 69·2 per 1,000 respectively, against 33·7 and 135·4 in the previous year.

Bombay. The total population of the six lunatic asylums of the Bombay Presidency (Colaba, Ratnagiri, Poona, Dharwar, Ahmedabad, and Sir Cowasji Jehangir, Hyderabad) was 1,006. including 292 fresh admissions, chiefly mendicants and beggars, against 978 in 1895. In the course of the year 192 patients were discharged, 72 of them as cured, and 78 died, leaving 736 under treatment at the close of the year. There was more sickness in the asylums than in 1895, the daily average sick having increased from 45 to 47, and the death-rate rose from 94·7 per 1,000 of average strength to 107·8. Of the 78 deaths, 20 were due to dysentery, 8 to epilepsy, 9 to chronic pneumonic phthisis, and 5 each to pneumonia and Bright's disease. The death-rate was higher in all the asylums, excepting Poona and Hyderabad. In the Colaba Asylum the death-rate rose from 123·7 to 185·6.

Medical Schools.

Bengal. The number of medical schools open in Bengal during 1896–97 was 11. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided—three being schools of homœopathy, one of electro-homœopathy, and two of allopathy. The college is affiliated to the University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the seven unaided schools (two at Dacca and five at Calcutta) follow their own standards for private practice. The total number of pupils attending the various medical schools in the province was 1,910, as compared with 1,854 in the previous year.

The total strength of the Calcutta Medical College at the beginning of the session in 1896–97 was 468 (including 10 women), against 511 in the preceding year. As regards the examinations, 237 candidates (including seven women) were successful out of a total of 445 (including 10 women), the successes being at the rate of 55 per cent., as compared with 57 per cent. in 1895–6. Of the 237 successful candidates, 87 passed the Preliminary Scientific L.M.S. examination, 48 (including three women) passed the first, and 27 (including one woman) the second L.M.S. examinations; 61 (including two women)

passed the Preliminary Scientific M.B. examination; five passed the first and four (including one woman) the second M.B. examinations; nine native dais passed in midwifery from the Eden Hospital, and received certificates of qualification, and 18 pupil nurses also passed as midwives.

The Campbell Medical School had 255 pupils (including 23 women) on its rolls during the session. Of this number 50 males and 6 women passed the final examination for the diploma.

At the Dacca Medical School there were 143 pupils on the rolls (including six women). Twenty-two students of the third-year class passed the diploma examination. No female student has as yet passed the final examination from this school.

The Temple Medical School, Patna, had 132 students (including 4 women) on its rolls. At the diploma examination 52 candidates appeared, and 42 passed, including two women.

At the Cuttack Medical School there were altogether 112 pupils (including five women). At the diploma examination 32 candidates (including one woman) appeared, and 30 passed, including the woman. The other two candidates who failed in one subject only were remanded for three months.

North-Western Provinces and Oudh.

The number of pupils of the various classes of the Agra Medical School who attended the examination at the close of the year 1896–97 was 252 (including 54 women), as compared with 264 at the end of the preceding year. The results of the final examination of male students show that 41 out of 46 candidates passed. All the 10 military students in this class passed, and 26 of the 31 civil students passed. Of the students in Class II., comprising second-year military and third-year civil, private, and Rajputana pupils, all the six military pupils passed the first half professional examination, and 48 out of 58 civil pupils. "On the whole," it is reported, "the average marks obtained by the "civil students were lower than in the previous year, while five failed to obtain "qualifying marks."

As regards women students, the year's working shows that 51 out of the total of 54 were examined, and that 15 passed; seven out of eight in Class I., and eight out of 15 in Class III. The first student in Class I. who gained the Viceroy's silver medal and the Dufferin prize obtained the high total of 765 out of a possible maximum of 900 marks.

Punjab.

The total number of students at the Lahore Medical College and School during 1896–97 was 445, or 24 less than in the previous year. Of these, 238 were in the College Class, and 207 were in the Medical Schools. The result of the year's examinations were on the whole favourable. Two students appeared at the first examination for the M.B. degree, and both passed, and 82 at the first L.M.S. examination, of whom 37 or 45 per cent. passed. In the second L.M.S. examination 9 passed out of 28, and in the second M.B. examination the single candidate passed.

In 1894 a medical school for women, called the North India Medical School for Christian Women, was opened at Ludhiana. The object of the institution is "to provide a thorough "medical training, under fully qualified Christian women, for those Christian women and "girls who wish to prepare themselves for medical mission work." No statistics have yet been received, but at the end of 1896 there were 24 students on the rolls, and they were reported to be making satisfactory progress.

Madras.

The total strength of the Madras Medical College during 1896–97 was 482. Of these, 28 were women students. In the Hospital Assistant Department, consisting of 220 pupils, 73 appeared for examination, of whom 69 passed, 26 being placed in the first class. The results of the several University examinations were again satisfactory, 42 having passed out of 65 candidates entered, against 48 out of 71. In the College Department there were 41 (including one woman) regular students reading for the M.B. and C.M. degree, 34 (including one woman) reading for the L.M.S. degree, and 15 casual students. The percentage of passes to the total examined at the University examination was 64·6, against 67·6 in the previous year.

Government having decided to close the Board Medical School at Nellore, no admissions were made into the school during the year, there were, therefore, only five students who were in their final course of study. At the Prince of Wales' Medical School, Tanjore, there were 35 pupils on the rolls, the highest number on record. At this school candidates are prepared for the Hospital Assistant examination.

Bombay.

The attendance at the Grant Medical College, Bombay, on account of the plague fell from 305 in 1895 to 279 (including 20 women) in 1896. For the first University examination in medicine there were 103 candidates, of whom 35 qualified; and for the second examination in medicine 39 passed out of 89 candidates. For the final examination for the degree of L.M.S there were 36 candidates, and of these only 13 passed, 1 in the first and 12 in the second class. The college sustained a severe loss in the death from plague of Surgeon-Major Manser, whose "teaching," the Principal reports, "was of "an eminently practical character; his experience, too, in Indian diseases was great, and "his opinion was, therefore, of great value."

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The number of students was 203, and of these 35 passed the final examinations.

VII.—SANITATION.

In Calcutta further progress was made in the improvement of bustees, or clusters of Native huts. The supply of filtered water was increased, and the average daily consumption is now equal to 41·42 gallons per head of population for the town proper, and 10·94 gallons for the suburban area. In the course of the year the distribution pipes were extended about 1½ miles, bringing the total length up to 312 miles, and the total number of premises connected had reached 27,184. The supply of unfiltered water slightly decreased, the daily consumption per head of population being equal to 12·47 gallons, as compared with 13·43 gallons in 1895. At the close of the year (1896–97) the total length of sewers was a little over 209¼ miles, and the number of premises connected with them was 29,588, of which 448 connections were made during the year. The new drainage project for the municipality was in hand, but the progress made did not come up to expectations owing to the delay in the acquisition of land, which is said to be unavoidable under the present Act. Some improvement was made during the year in the conservancy of the port of Calcutta. Bengal.

The municipalities of the interior of Bengal spent Rx. 243,008 on sanitation, an increase of Rx. 15,244 on the sum expended in 1895. In addition, the municipalities and district and local boards spent Rx. 126,764 on sanitary works; and a further sum of Rx. 49,413 was contributed by private individuals for the same purpose. The most important works were the completion of the Howrah water supply and the Muzaffarpur drainage schemes, the extension of the Cossipur-Chitpur water supply, additions to the Serampore and Jalpaiguri drainage works, and the construction of drains and the improvement of the water supply at Bhagalpur. The disposal of night-soil continued to receive attention, and in many places improved methods for its disposal were adopted. The Sanitary Commissioner, however, notices that little progress was made during the year in the cultivation of trenching grounds and utilizing refuse as manure. Caste prejudices, he thinks, is largely responsible for this, though he declines to believe that it is so strong that it cannot be overcome. He suggests that municipalities should be required to cultivate their trenching grounds and exhibit the crops on market days, in order to show the superiority of the produce of manured soil. "Object lessons like these," he says, "will probably do more to ovecome caste prejudice than talking to people on "the subject."

The Sanitary Board held three meetings in the course of the year, when, among other important matters, they discussed the Berhampore water-supply project, estimated to cost Rx. 23,883, which the late Maharani Surnamoyèe generously undertook to defray. The work was in course of completion. A scheme for the supply of drinking water to the town of Cuttack, estimated to cost Rx. 22,500, which, however, had to be abandoned owing to the undertaking being beyond the means of the municipality. An alternative scheme for the supply of drinking water to the town of Midnapore was estimated to cost Rx. 25,000. A scheme was brought forward for improving the drainage of the town of Krishnagar, at a cost of Rx. 3,323. Schemes for remodelling the storm water outfall and draining the suburbs of Calcutta, amounting to Rx. 788,709, were approved by the Board. A scheme for supplying pure water to the town of Chittagong, at a cost of Rx. 23,790, was under consideration.

In the North-Western Provinces and Oudh the municipalities expended over 45 per cent. of their income on water supply, drainage, and conservancy. Satisfactory progress was made during the year with the Benares drainage project, which has been under construction for some years past; and in most of the municipalities possessing water-works, house connections were extended, and the quality of the water was good. Early in the year the Meerut water-works were opened, and those at Dehra-Rajpur were completed. During the year the sanitary condition of Naini Tal was investigated by a strong committee appointed by the Local Government, and a report on the subject was submitted in November. Towards the close of the year orders were issued by the Government for reconstituting the Sanitary Board and converting it from a consultative to an executive body, and arranging, so far as practicable, for the employment of an North-Western Provinces and Oudh

efficient sanitary agency to co-operate with it, and for the undertaking of a detailed sanitary survey of each district. The Village Sanitation Act, which had been found useful in certain districts to which it had been tentatively extended, was brought into force throughout the provinces. From lists forwarded to the Government by the Sanitary Board it appears that, between 1889 and 1896, 255 drainage projects have been completed by the Irrigation Department, at a cost of Rx. 117,413, while on the 1st April 1896, 50 works were in progress at an estimated cost of Rx. 43,500, and for the next three years the programme comprises the construction of 104 drainage works, at a cost of Rx. 54,681, these being arranged by districts in order of urgency.

Punjab. In the Punjab the municipal towns spent 21 per cent. of their income on sanitary work. During the year the water-supply schemes of Delhi, Umballa, and Haripur in the Hazara district, were completed, as was also an extension to the waterworks scheme of Simla, at a cost of Rx. 33,121. The water-supply project of Bhiwani was commenced, that of Ludhiana was in progress, and that of Ferozepore under consideration. In Delhi a portion of the drainage scheme was completed, and estimates for the remainder were sanctioned. Drainage projects for Lahore, Mooltan, Gujranwala, Rawalpindi, and Hazro were in progress. A scheme for draining the flooded area of the Karnal district was undertaken, and an estimate was under preparation for extending the Simla sewage scheme. Besides these, several works of public utility were constructed by private individuals, at their own expense, to serve sanitary purposes.

The Sanitary Board met twice during the year, when they considered, among other matters, the drainage scheme of the city and cantonment of Ferozepore; statements drawn up by the Officiating Chief Engineer, describing the sanitary conditions of the municipal towns, and suggesting improvements; and the prevalence of fever in the province, specially in swampy and water-logged areas, and the remedies that might be applied.

Burma. The towns and districts of Burma spent nearly 35 per cent. of their income on sanitary improvements. No important work was undertaken during the year, but municipal committees are reported to have devoted a considerable share of their attention to the subject, and expenditure was incurred on the preliminary experiments and surveys, which are necessary before a mature scheme can be elaborated. In Rangoon experiments were carried out throughout the year, with a view to testing the efficiency of tube wells as a permanent source of water supply; and schemes for improving the water supply were being considered by the municipal committees of Bassein and Akyab.

The work of the Sanitary Board was again restricted to the provision of suitable sanitary maps of the larger towns.

Central Provinces. Sanitary reform in the Central Provinces was interrupted during 1896 by scarcity and subsequent famine. The municipalities expended 16 per cent. of their income on conservancy, drainage, and waterworks. The most important works undertaken or in progress were schemes for supplying water to certain municipalities. The Jubbulpore waterworks were further extended during the year. The Khandwa works were practically completed, progress was being made with those at Wardha and at Harda, and a water-supply scheme on a small scale was under consideration at Hoshangabad. The system of village sanitary inspection books has been introduced in several districts, but little progress was made in filling them in with the information required, owing to the heavy duties falling on civil surgeons in connection with the famine.

The Sanitary Board met in each of the four divisions during the year, when proposals and estimates for schemes of sanitary improvement in the various districts were considered.

Assam. Excluding the towns of Hailakandi, Sunamganj, Karimganj, and Maulvibazar, which have no separate incomes of their own, the municipalities, stations, unions, and towns in Assam spent 46·10 per cent. of their income on sanitation. No extensive sanitary work was undertaken during the year, but the waterworks of Shillong were put into an efficient condition and greatly improved, and the experimental well at Sylhet, with attached reservoir and taps, was completed. The sanitary improvements effected in rural tracts were comparatively unimportant, though some progress was made in the direction

of providing a purer water supply by the construction of masonry wells at some of the larger villages and market places, and the maintenance and repair of existing wells and tanks. No meeting of the Sanitary Board was held during the year.

Madras.

In Madras Presidency the municipal councils allotted 48·1 per cent., and the district boards 8·4 per cent., of their income for sanitary purposes. "It cannot be said," the Sanitary Commissioner states, "that the rate of sanitary progress in municipalities "is such as to render the sanitarian sanguine. Still, progress is apparent, and this "being so, it may be assumed that reforms will be introduced in an ever-increasing "ratio, as one improvement is almost necessarily followed by another, with the "object of securing full results." During the year the water-supply works at Trichinopoly and Dindigul were completed and opened. Similar works were also in progress at Conjeeveram and Kurnool. Village sanitary inspection report books were in use in all unions in 19 out of the 22 districts of the Presidency at the end of the year, the exceptions being Vizagapatam, Anantapur, and Cuddapah.

The Sanitary Board scrutinised plans and estimates for 72 municipal and 87 local fund works, of the aggregate cost of Rx. 27,533. The Sanitary Engineering Department completed surveys for water-supply or drainage for seven municipalities. Six schemes, costing Rx. 198,954, were submitted to the Sanitary Board, and of these the water-supply of Srirangam, Kumbakonam, Gudiyattam, and the construction of filter-beds, and a service reservoir at Cuddapah, were submitted to Government by the Board, and two schemes for the water-supply of Tuticorin and Bellary were under the consideration of the Board. Schemes were also under preparation for the water-supply of Negapatam and Coonoor, and for the drainage of Cuddapah, and revised estimates for five schemes of water-supply were prepared, costing Rx. 173,657. The movement inaugurated under the advice of the Sanitary Commissioner in 1894 to obtain properly qualified Sanitary Inspectors was making satisfactory progress. In 1896, 52 men were granted the necessary certificates, and it is now compulsory for each municipality to entertain one trained man. Twenty-eight councils now employ certificated inspectors, four are employed by District Boards, and provision has been made in the Budget for 1897-98 for five more.

In improving the sanitation of Madras City, several useful improvements were being carried out. The water-supply was extended, and there was an appreciable improvement in the quality. The quantity supplied to the town was nearly one-fourth in excess of that in the previous year. The long-contemplated scheme for the drainage of the city has been taken in hand, the Commissioners having commenced with the drainage of Mylapur. It is, however, observed, "that it will be several years before the drainage scheme is "completed, and until this is done, and the proposed improvements in the water-supply are "effected, Madras cannot be expected to become a healthy town."

Bombay.

In Bombay Presidency the municipalities allotted 45·29 per cent., and the district boards 17·12 per cent., of their income for sanitary purposes. During the year improvements to the waterworks at Karachi and Sukkur were executed; good progress was made in those at Surat and Yeola; while those at Jalgaon and Dhulia were completed. The experimental portion of the sewerage scheme at Ahmedabad was completed, at a total cost of Rx. 38,350, as were also the surface drainage works at Nasik. The Bombay Village Sanitation Act of 1889, under a modified form, has been brought into force in all the districts except Kanara and Upper Sind Frontier.

The Sanitary Board gave advice concerning a large number of projects, including the waterworks of Surat and Rander, Malegaon in Nasik district, Islampur, and Satara, the sewage farm at Ahmedabad, and other sanitary schemes which had been submitted to them.

In Bombay City the Shone system of sewerage at Colaba worked uniformly during the year. In other divisions drainage and sewerage works were in progress, while several new works were commenced. The water-supply of the city from the Tansa, Vehar, and Tulsi lakes continued to be adequate; structural and other improvements in the reservoirs were being carried out.

Berar.

The municipalities of Berar spent 74 per cent. of their income on sanitary improvement. No new works of any great importance were undertaken during the year, but the Kapsi water-supply scheme for Akola was completed, and the Buldana drainage scheme made progress. The District Boards allotted a sum of Rx. 10,683 for sanitary works; of this amount over 77 per cent. were spent during the year, chiefly on water-supply, drainage, and conservancy.

The District Sanitary Boards met once at each of the six headquarter stations. They considered the measures taken by local bodies to give effect to the recommendations of the Provincial Sanitary Commissioner, and recorded their suggestion against each incomplete work. Proposals to legalise a system of village sanitation were circulated throughout the province for the purpose of eliciting native opinion on the subject. About 70 replies were received, all objecting to any legislative interference with the customs of the people in connection with sanitary reform.

ABSTRACTS

OF

SANITARY AND OTHER REPORTS

FOR

1896.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1896.

(*Surgeon-Major-General J. Cleghorn, M.D.*)

LIBRARY OF THE BOMBAY BRANCH OF THE ROYAL ASIATIC SOCIETY

European Troops.

Sickness and mortality in 1896.

THE health of the European army of India was better in 1896 than in the preceding year, though invaliding increased somewhat.

European Troops in India.

YEAR.	Strength.	RATIO PER 1,000 OF STRENGTH.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	TOTAL LOSS.
1886–95	677,877	1,457	83	15·16	24	39
1895	71,031	1,462	94	15·26	23	39
1896	70,484	1,387	94	14·84	28	43

The chief causes of admission were venereal diseases and ague. Among the diseases with increased admission-rates were small-pox, influenza, cholera, and hepatitis. On the other hand, the admission-rates from ague, dysentery, diarrhœa, and enteric fever were lessened. Venereal diseases caused 37 per cent. of the total sickness, and ague 17 per cent.

The chief causes of death were enteric fever and hepatic abscess. Among the diseases with increased mortality were cholera, small-pox, and circulatory diseases. On the other hand, the mortality from ague, dysentery, diarrhœa, hepatic abscess, and enteric fever was lessened. Enteric fever caused nearly 43 per cent. of the total deaths, and hepatic abscess 8 per cent.

The chief causes of invaliding were, in order, syphilis and gonorrhœa, debility, tubercle of the lungs, and malarial fevers.

Owing to the system in force for the returns of the army, the following tables must be read with the reservation that the months shown are not really calendar months, but variable periods of from 4 to 5 weeks. However, though the month-headings are not exact, they sufficiently indicate whereabouts in the year or period a maximum or minimum falls. The first table deals with the admission-rate, the second with the constantly sick-rate, and the third with the death-rate, and all are quite or nearly self explanatory. A few remarks may, however, be useful. The first shows that the whole year ratio of 1895 and 1896 were lower than the ratio of the quindecennium ; and that the ratios of all the

months of 1896 after March were lower than their corresponding quindecennial ratios:—

Period.	Admission ratio per 1,000 per annum.												For the Period.
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	
1880–94	1270·8	1204·6	1272·4	1439·1	1476·6	1479·2	1529·7	1607·2	1744·9	1758·5	1643·9	1365·1	1484·2
1895*	1368·3	1287·3	1375·5	1467·4	1559·5	1547·0	1597·9	1503·2	1476·9	1535·4	1450·8	1363·5	1460·0
1896 ...	1344·0	1294·5	1331·8	1373·1	1360·0	1413·3	1515·8	1452·7	1439·2	1443·6	1401·4	1215·8	1386·7

* Excluding Field Forces.

It also shows that while the maximum monthly ratio for the fifteen-year period was that of October, both 1895 and 1896 had their maximum in July. The next shows that the whole-year constantly sick ratios of 1895 and 1896 were considerably higher than the ratio for the quindecennium, and that every month of 1896 had a higher ratio than the corresponding quindecennial month. The increase of the constantly sick-rate of recent years was attributed on page 16 of the report for 1895 to the increase of enteric fever and venereal affections, diseases which Table IV. shows to occur in large numbers, and to necessitate a long stay in hospital. To these may be added influenza, especially in some of the years from 1890 onwards.

Period.	Constantly sick-rate per 1,000.												For the Period.
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	
1880–94...	76·3	75·3	69·6	69·4	74·4	76·0	78·3	81·1	84·2	80·8	78·7	74·8	76·6
1895* ...	97·5	91·5	87·0	90·2	93·9	95·7	97·1	97·2	94·2	92·5	93·3	93·6	93·6
1896 ...	98·8	94·9	93·6	90·8	91·7	92·2	95·7	97·7	98·1	92·7	92·8	87·2	93·8

* Excluding Field Forces.

In addition, the above shows that while the maximum month in the fifteen-year period was September, the maximum of both 1895 and 1896 was in January. In 1896 this was due to the prevalence of influenza and pneumonia in the end of 1895 and beginning of 1896; and in 1895 there seems to have been an unusual amount of malarial and enteric fevers at the beginning of the year. The third table shows that the whole-year ratios of 1895 and 1896 were below the ratio of the quindecennium, and that after July all the monthly ratios of 1896 were below the corresponding quindecennial ratios:—

Period.	Death ratio per 1,000 per annum.												For the Period.
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	
1880–94...	11·52	9·49	9·51	13·68	16·88	19·36	17·73	21·14	21·64	16·85	14·29	12·88	15·46
1895* ...	9·06	8·18	6·36	14·59	21·40	19·95	14·67	18·51	15·44	13·10	11·48	13·66	13·79
1896 ...	14·81	8·45	15·48	20·37	18·60	14·96	19·86	17·77	14·05	11·93	10·24	10·98	14·84

* Excluding Field Forces.

It shows, too, that 1895 and 1896 had their maximum month of mortality earlier in the year than that of the fifteen-year period.

In the following table the ratios of the four commands are placed side by side for comparison. Bengal had the highest mortality from cholera, enteric fever, ague, tubercle of the lungs, dysentery, and hepatic abscess ; the Punjab the highest from remittent fever, heatstroke, and pneumonia, and the lowest from cholera, small-pox, tubercle of the lungs, and dysentery ; Madras the lowest from enteric fever, heatstroke, and pneumonia ; and Bombay the highest from small-pox and respiratory diseases other than pneumonia. The percentage of enteric fever in total deaths was greatest in the Punjab, and the percentage of hepatic abscess in Bengal. The total death-rate of Bengal, which was the highest, was not far from being double that of Madras, which was the lowest. Only the Punjab command was more healthy than in the previous year :—

Ratios of Commands.

The following table gives vital statistics of the European troops in Burma as a whole :—

Period.	Strength.	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths from		
				Cholera.	Other causes.	Total.
1890	4,712	1,743	102	—	20·80	20·80
1891	4,623	1,589	92	2·38	17·74	20·12
1892	4,316	1,491	91	—	14·83	14·83
1893	3,928	1,461	96	·25	12·73	12·98
1894	3,940	1,465	93	·25	9·39	9·64
1895	4,045	1,410	96	·99	8·41	9·39
1896	4,174	1,514	109	·48	6·71	7·19

Burma in 1896 was distinguished by the prevalence of influenza, simple continued fever, and hepatitis.

The following table shows that, judging by the constantly sick-rate, Burma Inland and Gangetic Plain were the most unhealthy for the decennium, and the Hills and the Deccan the most healthy. It also shows that the 1896 constantly sick-rate of every group, except Bengal-Orissa, Western Coast, and Southern India, was higher than its corresponding decennial ratio, and that the rise was greatest in the cases of Central India, Burma Coast, and the Hills. As compared with the decennial ratios, there was increase of cholera mortality in six groups, and of enteric fever mortality in eight :—

In the following table the vital statistics of the groups for 1896 will be found placed side by side to facilitate comparison. Central India had the highest constantly sick and admission rates ; Gangetic Plain the highest death-rate ; Western Coast the lowest constantly sick and admission rates ; and Southern India the lowest death-rate. Burma Coast had the highest admission-rates from influenza, hepatitis, and the lowest from remittent fever ; Burma Inland the highest from simple continued fever, and the lowest from enteric fever ; Bengal-Orissa the highest from remittent fever, dysentery, and hepatic abscess ; Upper Sub-Himalayan the highest from pneumonia ; Indus Valley the highest from ague ; Central India the highest from cholera, respiratory diseases other than pneumonia, and venereal diseases ; the Deccan the highest from tubercle of the lungs ; Western Coast the lowest from ague, tubercle of the lungs, dysentery, hepatic abscess, hepatitis, and

venereal diseases; Southern India the highest from small-pox, and the lowest from diarrhœa; the Hills the highest from enteric fever, rheumatic fever, and diarrhœa:—

All Causes	11·45	5·60	17·07	22·42	13·83	14·47	19·72	14·67	17·99	11·23	12·53	12·53	14·84

The percentage of enteric fever to total admissions in 1896 was greatest in the Hills; of ague in the Indus Valley; of remittent fever, dysentery, and hepatic abscess in Bengal-Orissa; of simple continued fever in Burma Inland; of pneumonia in Upper Sub-Himalayan; of other respiratory diseases in Burma Coast and Upper Sub-Himalayan; and of venereal diseases in the Deccan.

The highest ratios among the large garrisons with a strength of over 1,000 were those of Allahabad, Fyzabad, Lucknow, and Agra. Those of the last two were lower than in the preceding year; that of Fyzabad only slightly higher, while that of Allahabad was more nearly four than three times higher. The cause of the great rise at Allahabad was an increase of enteric fever.

The statistics of individual regiments show that the infantry had the highest admission and constantly sick rates, as in the previous year; the artillery the highest invaliding rate, as in 1895, and the highest death-rate. The 1st battalion, Royal Welsh Fusiliers, at Jhansi, had the highest constantly sick ratio among infantry regiments, and the 1st Norfolk at Allahabad the highest death-rate. The latter regiment suffered severely from enteric fever, to the extent of 93 admissions and 32 deaths.

Principal diseases: Influenza.

Sickness and mortality having been studied in their relation to India, to commands, to geographical groups, to stations, and to regiments, it will be convenient now to discuss the statistics of some of the chief diseases. Influenza, which had been rising in the end of 1895, reached a maximum in January 1896, and after two temporary rises, one in March and the other in September-October, fell again in the last two months of the year. The following shows the increase in 1896 over 1895. It also shows the fluctuations of the disease since 1890, the first epidemic year:—

Period.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Per 1,000 of strength.
1890	—	3	473	1,451	248	69	13	2	3	—	—	1	2,263	33·4
1891	1	—	1	16	77	91	112	29	20	2	2	21	372	5·5
1892	113	53	354	241	57	4	32	8	—	—	—	—	862	12·7
1893	1	—	—	15	4	—	—	—	—	—	—	1	21	·3
1894	7	9	12	70	101	30	7	7	—	2	—	—	245	3·4
1895	14	7	52	156	66	35	17	1	5	13	23	165	554	7·8
1896	262	65	140	30	12	7	3	3	88	128	50	20	808	11·5
Total	398	137	1,032	1,979	565	236	184	50	116	145	75	208	5,125	

The actual maximum of the individual years of the seven occurred in various different months, but over the seven-year period as a whole the greatest number of cases occurred in April and March, and the smallest number in August and November; 85 per cent. of the whole in the first six months of the year, and only 15 per cent. in the last six months. Geographical Groups I., II., V., VI., VII., VIII., IX., XI., XII*a*., and XII*b*., were attacked both in 1895 and 1896; while Groups IV. and X. were spared in both years, as well as in 1894. Twenty-five stations were attacked in 1896 against twenty-three, nine of them suffering only in 1896, sixteen in both years, while some escaped that had been affected in 1895. Among stations, Lucknow, Rangoon, Bareilly, and Secunderabad had the greatest numbers of cases. There were two distinct outbreaks at Rangoon, while at Bareilly the disease was confined to the first three months, and at Lucknow to the last four months of the year. Rangoon had a large number of cases in the preceding year also. The average number of men constantly sick with influenza was 61, against 16 in 1895, and the average duration of a case 28 days against 10. The returns deal, of course, only with those cases which were admitted into hospital, but there were mild cases not admitted. On page 68 is given a table showing the relation year by year of influenza to pneumonia, and of the influenza of the European troops to that of the native troops and to that of the prisoners.

Cholera.

General questions regarding the etiology, spread, and prevention of cholera, and the circumstances attending the most important outbreaks of 1896, are discussed in pp. 89–101 and 143 and 144.

The amount of cholera was greater than in the previous year, but the ratios were lower than those of the decennium, as may be seen in the following table :—

Period.	Admissions.		Deaths.	
	Number.	Per 1,000 of strength.	Number.	Per 1,000 of strength.
1886–95	1,280	1·9	901	1·33
1895	44	·6	32	·45
1896	70	1·0	63	·89

The disease was at its maximum in March ; there was none of it before March or after August ; and Poona with 13 cases, Benares and Jhansi suffered most.

Small-pox.

The admission-rate from small-pox was nearly six times, and the death-rate nearly five times, as great as in 1895. There were 122 cases with 10 deaths, against 19 cases with 2 deaths. The death-rate was also more than one and a half times the decennial ratio of 1882–91. The greatest numbers of cases at individual stations were 17 at Bangalore, 16 at Allahabad, 9 each at Rawalpindi and Umballa, 7 at Meean Meer, and 6 at Meerut. This list of stations itself shows that the disease was widespread ; but it may be stated in addition that each of the four Commands had much increased admission ratios. In Burma Coast, Bengal-Orissa, and Western Coast small-pox was absent, as in the preceding year ; and in the Deccan there was less ; but in all the other groups there was an increase, mostly large.

Fevers.

Ague gave rise to about 17 per cent., an unusually low proportion, of the admissions from all causes. The year 1896 was a very dry one, and naturally it was also comparatively non-malarious :—

Period.	Intermittent Fever.		Remittent Fever.		Simple Continued Fever.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	353	·18	9	·54	57	·04
1895	336	·25	13	·30	22	·04
1896	239	·10	14	·40	30	—

The preceding year had also been dry and non-malarious, but not to such a degree as 1896. In 1896 ague ratios were high in Indus Valley, Central India, and Upper Sub-Himalayan, and low in Western Coast and Southern India. And that that is a usual state of things may be seen from the following :—

Period.	Ratio per 1,000 of Strength.												
	I. Burma Coast and Bay Islands.	II. Burma Inland.	IV. Bengal and Orissa.	V. Gangetic Plain and Chutia Nagpur.	VI. Upper Sub-Himalayan.	VII. North-Western Frontier, Indus Valley and North-Western Rajputana.	VIII. South Eastern Rajputana, Central India, and Gujarat.	IX. Deccan.	X. Western Coast.	XI. Southern India.	XII*a*. Hill Stations.	XII*b*. Hill Convalescent Depôts and Sanitaria.	India.
1886–95...	194·5	531·2	381·8	216·9	465·5	632·4	496·9	228·0	164·3	119·0	291·0	320·4	352·9
1895 ...	176·9	140·8	339·5	166·5	415·6	952·9	337·9	249·7	72·3	101·3	268·9	421·7	336·0
1896 ...	105·3	157·1	204·9	183·4	248·7	523·5	376·1	265·1	75·8	80·3	163·9	178·8	239·0

Since Upper Burma has become settled and the soldiers less exposed, there has been a great reduction in malarial fever in the Burma Inland group. The most malarious month of 1896 was September, and the least malarious February. At Fort Lahore the water was regularly boiled, attention was paid to clothing, and 5-grain doses of quinine were given daily during October and November.

Though there was no field service in 1896, there was again an increase in remittent fever, as shown above. The principal increase was in Burma Coast, Upper Sub-Himalayan, Indus Valley, and Southern India. None of the medical officers seem to have regarded the disease as of sufficient importance to call for remarks, but at Rangoon and Amritsar it was stated to have been mild in type. All the fatal cases were ascribed to malaria, and the *post-mortem* appearances recorded were compatible with that diagnosis, though in one case there was a small superficial abscess of the liver, and in another there might be some suspicion of septicæmia. Remittent fever was most prevalent in June and in the period June-October.

The rise in simple continued fever was perhaps what might have been expected in a dry hot year; the maximum was in June. Medical officers sometimes note that cases returned as simple continued fever may have been mild cases of enteric fever; and they differ in practice as to where they draw the line between simple continued fever and enteric fever, as well as between simple continued fever and ague. A recent writer has stated his belief that ardent fever may develop into enteric fever, or at least into *an* enteric fever.

On page 26 of the report for 1892 (page 53 of "Report on Sanitary Measures in India in 1892-93," vol. xxvi. [C. 7192]) a hint was dropped as to the possible occurrence of Malta fever in India. Since then the actuality thereof has been positively asserted as regards certain stations, more especially Subathu, on the ground that the blood-serum of some soldiers invalided from those stations was found at Netley to react specifically with the *micrococcus Melitensis*. The subject deserves further investigation, preferably in India itself. By the use of the method of serum diagnosis it is said to have been shown that the *micrococcus Melitensis* is the true cause of Malta fever; that Malta fever occurs in India; that certain cases which had been diagnosed as enteric fever were really cases of Malta fever; that certain cases which had been diagnosed as enteric fever were cases neither of enteric fever nor of Malta fever, but either malarial or of some as yet undifferentiated class; and that the agglutinating and sedimenting power of patients' serum persists for years. If the very promising method of serum diagnosis fulfils all that is hoped and expected of it, a certain measure of the light of certainty will be thrown upon the differentiation of Indian levers.

Enteric fever.

In the matter of enteric fever the differentiation of the bacillus and the treatment of the disease by enteric serum, the diagnosis of the fever by the patient's serum-reaction to a true cultivation of the specific bacillus, preventive inoculation or vaccination, and the question as to how wide may be the dissemination of the enteric bacillus in nature, continue to be the chief topics of interest. Just as when tubercle bacilli gaining access to a blood vessel are carried to all the parts supplied with blood, and produce general tuberculosis, so was the enteric bacillus distributed by the water pipes at Maidstone. A different mode of water-conveyance, its effectiveness doubtless aided by other factors, such as exposure, fatigue, low spirits, fear, &c., is described by a writer in the "Indian Medical Gazette," who says that after the earthquake of the 12th June there was a smart outbreak of enteric fever among the younger residents of the station of Shillong, the cases occurring simultaneously. The earthquake had damaged the waterworks, and people were obliged to have recourse to water from impure sources. "This," he says, "is one more instance "of the dependence of enteric fever on the drinking of impure water, and it further opens "up the question as to the widespread distribution of the typhoid bacillus."

The modern view regarding the value of the chemical and bacteriological examination of water as a guide may be summed up as follows, more or less in the phraseology of the late Sir George Buchanan:—"They can tell us of impurity and risk, but cannot guarantee "purity and safety. Besides utilising the aid of the chemist and the bacteriologist, we "must learn the geological source and history of the water, and must go in search of the "conditions surrounding and affecting the source and storage."

Hankin, who stated that the water of some Indian rivers possessed a bactericidal power against the cholera microbe, finds that the enteric bacillus is not affected by the same water.

Abba, working under certain experimental conditions with Pasteur-Chamberland filter-candles, found that one or two kinds of the water bacteria could grow through the candle in about ten days, while the cholera commas, the enteric bacillus, and the *bacillus coli*,

could not get through. The bacteria which can pass the filter are, he says, such as find in the water an environment favourable to growth as well as to life.

In connexion with the question of water a paper on the liability of total abstainers to enteric fever may be here referred to; and the danger of the spread of infected water through the medium of milk is illustrated by another.

The possibility of air and dust-borne enteric fever is held by some; but Germano has shown by a series of experiments that the enteric bacillus cannot survive thorough drying, or such a degree of drying as would allow it to be carried away by currents of air. But, as he proves, it can not only exist for a long time in moist media, but can also survive under certain circumstances in an apparently dry condition, provided it adheres to articles, or is surrounded by materials, which preserve a certain amount of moisture in themselves, such as linen, articles of clothing, wood, heaps of earth, dust, and fæces-containing dirt. Even in such circumstances most of the bacilli die, but a few survive. These cannot become a danger by getting into the air, because that would require so fine a crumbling that complete dryness, and therefore death of the bacilli, would result. But the danger is that they may get on to the fingers, on to food, on to dishes, and so into the mouths of susceptible men. Just this property of the enteric bacilli to survive a long time in a half dried condition, concludes Germano, must be considered as one of the chief sources of enteric infection. Sinnhuher also found that in pulverised garden earth kept in a moist state cholera and enteric bacilli retained their vitality for several months, perhaps for indefinite periods.

In India, as elsewhere, enteric fever has sometimes been supposed to be conveyed in bread. Arloing, however, points out that while the enteric bacillus dies at 60° C., the temperature of an oven reaches 200° C., and the central part of the bread during baking 110° C. He placed rich cultures of the enteric bacillus in pipettes in the middle of loaves, and then baked the loaves for from 15 minutes to one hour. All were rendered sterile; and he concludes that "one can therefore lay down that, even if bread be prepared with "water containing Eberth's bacillus, the baked bread will be harmless."

Dwouieglazoff in 37 examinations of 15 patients' mouths found the enteric bacillus twice, but not at all in 10 similar examinations of the attendants.

Laveran mentions that in the case of an outbreak in a military depôt in France the enteric bacillus and fragments of tape-worm were found on the leaves used for salad by the non-commissioned officers, who alone were affected, and he specially warns against strawberries as likely carriers of infection. This latter may very likely be one of the modes of conveyance of the disease in the Himalayan hill stations of India.

Ransom in a lecture stated his strong belief in the spread of enteric fever by personal contagion, and he gave several instances occurring in the case of nurses and hospital attendants. He reminded his hearers that the vitality of the bacilli is considerable, and that they may be found not only in the fæces but also in the urine and sputa, and live long outside the body; and that the necessary precautions were prevention of dried excreta reaching the dust of the room or the clothes of the nurse, as well as the careful washing and disinfection of the hands of the latter, and the disinfection of the patient's stools.

Continuing the subject of the spread of enteric fever, the following are some facts regarding Widal's test with mother and fœtus. A child was born when the mother was in the about third week of the disease; it was healthy except for slight transitory jaundice; when the child was about 7 weeks old its blood serum gave a positive reaction, so that "either the agglutinating principle had passed from the mother's into its blood, or, more "probably, it had had enteric fever." A woman suffering from enteric fever at about the fifth month of pregnancy gave the reaction; she recovered; the child was born about four months afterwards; when the child, which was breast-fed, was five weeks old its blood failed to react, while the mother's, tested at the same time, reacted positively. The inoculation of a pregnant guinea-pig lent a weakened reaction to the blood of the fœtus. In a nearly full term fœtus of a mother affected with enteric fever both the enteric bacillus and the staphylococcus were found in the blood, spleen, and liver. Enteric bacilli were found in the blood of a fœtus aborted on the 29th day of its mother's fever. In one case the placental blood gave a positive reaction, while the reaction of the fœtal blood was negative. The occurrence of enteric fever has been reported in a little female child of $13\frac{1}{2}$ months nourished at the breast.

A belief in the spread of enteric fever by sewer gas still lingers, but there is perhaps more ground for fear as to pollution of the soil, and of the floors, &c., of buildings.

As Kanthack says, the virulence of many organisms may also be permanently or temporarily increased, either by changing the composition of the nutrient medium in or on

which they grow, or by passing the organisms through a series of animals (a process which is called passage), especially if the animals be relatively insusceptible. In some cases, however, continued passage will lead to permanent attenuation, an important observation in so far as it helps to throw light on the natural decline of many epidemics, which may cease by virtue of a gradual attenuation brought about by continuous transmission from man to man. Again, Kollman found in the case of guinea-pigs that by means of five rapidly successive inoculations from animal to animal the virulence of the enteric bacillus could be doubled ; and that by two-hourly inoculations the *bacillus coli* had its virulence increased five times. Cultivated on ordinary media these bacilli rapidly began to lose the extra virulence ; and to maintain it an occasional passage through animals was found necessary. Even, therefore, if it be confirmed that the enteric bacillus is widespread in nature, efforts against contamination by excreta must not on that account be relaxed ; for not only do these excreta contain the bacillus, but its virulence therein may be greater than in outside nature, and its virulence may be liable to still further increase by passage through another human body.

It is not known upon what statistics is based the assertion that natives of India when they emigrate to other countries suffer more severely from enteric fever than in their own country, and that the disease has been observed among native troops sent to Hong Kong, North China, Singapore. The Army Medical Reports for the six years 1890 to 1895 show no deaths from enteric fever among the Asiatic troops of China and the Straits Settlements, and no mention is made of admissions. And the Abstracts given in the same reports indicate that the European troops stationed there suffer in less proportion than those in India. See also the Report of the Sanitary Commissioner with the Government of India for 1895, paragraph 17, pages 36 and 37. The records of the Perak Expedition also make no mention of the disease.

It has been stated that British troops have suffered from enteric fever on virgin soil uncontaminated by man, and the remarks made by the medical officer of Quetta and quoted in paragraph 15 may, in this connexion, also be referred to ; but before accepting as an explanation of this the at present not completely proved saprophytic presence of the enteric bacillus in nature, the somewhat difficult task of proving the impossibility of previous human contamination would have to be undertaken.

Several fresh cases of enteric fever without intestinal lesions have been placed on record, and that the disease was really enteric fever was proved in some of them by the discovery of the bacillus in the spleen or bile. Very little work seems to have been done in India in the way of cultivation of the genuine bacillus from the spleen, though this is important both for the diagnosis of the individual case and for the preservation of a standard for laboratory use.

With regard to the occurrence of the bacillus in the urine some additional information has been published. Blumer in the examination of 10 cases of pyuria found the *bacillus coli* in 7, once along with the enteric bacillus ; and the enteric bacillus twice, once with the colon bacillus ; and he remarks that many of the results of the older investigators were wrong, because they mistook the *bacillus coli* for the enteric bacillus. Horton Smith made 61 observations on 7 cases. In 3 cases the urine contained enteric bacilli at some period of the disease, sometimes in enormous quantities. They first appeared in the third week or later. In one case they persisted in the urine for 22 days after the temperature had come down for good. He concludes, firstly, that the examination of the urine is not of much use for diagnostic purposes, because of the late appearance of the bacillus in that excretion, and, secondly, that the urine may sometimes be a serious source of infection.

Kuhnau reports that from the blood taken in a droplet from the finger tip he did not once succeed in isolating the bacillus ; but in blood taken direct from a vein, and used in quantities of 5·10 cc., he found it in 11 out of 41 cases. Sanarelli, as was mentioned in a former report, considers enteric fever to be primarily a blood disease, and he has lately likened it to yellow fever, insomuch as both are blood diseases, and both result in a hæmatogenous enteritis.

In this present and in former reports reference has been made to cases in which enteric fever and dysentery appeared to co-exist or to be mistaken one for another. On this point the Davidsons say :—

"Enteric fever and dysentery may declare themselves simultaneously in the same patient, "and this double infection has been observed occasionally to occur in an epidemic form . . . . . "As the disease advances the dysenteric symptoms yield, sometimes suddenly, to those of "typhoid fever."

The preventive measures usually proposed may be divided into such as are to kill or weaken the bacillus and such as are to strengthen the human being against it. The general aim of all measures of the first class may be shortly stated as cleanliness. But it may be doubted whether "universal public and private cleanliness" is attainable, and whether, if it were attained, enteric fever would be found to have been eradicated.

There is no doubt that for the disposal of excreta cremation is the most thorough and the surest plan, and it is practically convenient to mix the excreta with sawdust before incineration. But a very promising method is that recently described by Sinnhuher, who found that :—

"In pulverised garden soil, kept in a moderately moist state, cholera and enteric bacilli retained "their vitality for several months, perhaps for indefinite periods ; but they were speedily destroyed "by the addition of small proportions of quicklime thoroughly incorporated with the earth. "With 4 per cent. they perished in 4 hours, with 6 per cent. in less than an hour, and with "8 per cent. within 15 minutes. If kept fairly dry, the mixture lost its activity very slowly, not, "in fact, until the lapse of many weeks or months, while it was fully as efficient a deodoriser "as the pure earth. He therefore recommends as the best material for dry-earth closets a mixture "of 10 per cent. of quicklime with dry garden mould, stored under cover from the rain and "well worked together, as calculated to act as a disinfectant or germicide, as well as to render "excreta inoffensive to the smell without any deterioration of their value as a manure."

It is mentioned in paragraph 15 that great use has been made in India during 1896 of boiling, and of the addition of potassium permanganate alum, &c., for the purification of drinking water. Alum is said, however, to be powerless against the enteric bacillus.

The provision of better sources of supply and the use of the Pasteur-Chamberland filter are said to have greatly reduced the morbidity and mortality from enteric fever in the French army ; in 1886 the number of deaths was 964, in 1887 the reforms just mentioned were introduced, and the number of deaths has gradually sunk to 441 in 1896. French writers also point out the necessity for constant attention to the cleanliness of the floors and the wood-work of buildings, especially of those in which cases of enteric fever have occurred.

Many medical officers lay stress on the influence of youth and recent arrival, and some call attention to the increase of enteric fever in a station following the arrival of fresh drafts from England. Some nine or ten men were supposed to have contracted the disease on board ship, at Bombay, or on the way from Bombay to the up country station. Again, medical officers frequently noted, especially in the case of hill stations, that the disease must have been contracted before arrival, either from impurities encountered on the march, or from a cause existing in the previous station ; so that the station where the disease was treated was not always the station in which it was contracted. Some patients acknowledged having used foul or doubtful water in the jungle, on the rifle range, or when marching from the plains to the hills. A complaint was recorded of the dirtiness of camps on the march from the plains to the hills, and of the distance of the good water from a camp, and the nearness of bad water to it. At Bareilly and Nowshera it was noticed that men at the rifle range, or on signalling or field training, that is, men employed outside of barracks, were peculiarly liable to attack, whether from fatigue and exposure, or from being more likely to have recourse to the drinking of dirty water. The water supply was considered liable to contamination at Kasauli, Dagshai, Meean Meer, Ahmednagar, Meiktila, Shwebo, and Bernardmyo. The danger of a double water-supply, one for drinking and one for other purposes, is noted in the reports from Calcutta, Ranikhet, Madras, Bangalore, Wellington, Rangoon, Port Blair, Thayetmyo, Nasirabad, and Taragarh. In some cases there remained the danger of the supply by lazy servants of water from forbidden sources. There was a general feeling among medical officers that mussacks were dangerous, and their use was avoided as much as possible, or they were more or less systematically disinfected. But in two cases it was found that drinking water, after being boiled and cooled, was being distributed in, apparently non-disinfected, mussacks. In some cases it appears that dislike of boiled water or of water treated with permanganate of potash was the cause of men resorting to forbidden sources. At Hyderabad the intake of the water supply from the river was considered to be dangerously placed. The use of dip wells, the fouling of well-ropes by bullock droppings, the non-cleansing of water-pipes that had been lying about before they were laid, were alluded to

as sources of danger. At Cannanore and Mallapuram some of the cases were attributed to the drinking of bad water while on field service against the Moplahs. The combined result of five stations was that 46 cases occurred among total abstainers, and 129 in non-abstainers, or 26 and 74 per cent. respectively. But, as their average annual strengths cannot be obtained, no conclusion can be drawn as to the relative liability of those two classes. As usual, some medical officers point out the comparative immunity of women and children, and use it as an argument against the probability of the disease having been carried by the water or milk supplies. In a circular memorandum, dated Simla, the 12th May 1896, orders were issued by the Principal Medical Officer, Her Majesty's Forces in India, for the abolition of the Macnamara filters, and authorising the necessary expenditure for the use, according to circumstances, of alum, permanganate of potash, or boiling. The extracts given below will show how these instructions have been carried out, and with what results. In many cases, also noticed more fully below, the specific microbe was reported to have been discovered in the water or other article. When three officers of a mess at Meerut were attacked, no enteric microbe was found in their drinking water, but investigation showed that their milk was being supplied from the bazar. The medical officer at Dalhousie urges that, with all the modern minute attention to sanitary detail, there has not been any great practical result in the diminution of enteric fever in India; and, like many other medical officers, he considers the reason of this to be that the men contract enteric fever out of barracks, in the bazars. In support of the contention that enteric fever is mostly contracted in the bazars and especially in the brothels, the medical officers at Fort Allahabad, Meerut, and Nasirabad point out that it was the bachelors who were attacked, and that the married families escaped. In some cases it was noted that men admitted with venereal disease were apt to develop enteric fever, and that placing the bazar out of bounds effected a diminution of enteric fever; but at Nasirabad placing the bazar out of bounds is said to have done no good. The danger in the careless and dirty habits of the native cooks is insisted on by several medical officers, and two of them suggest that the soldiers should be made to cook for themselves, as in England. In some stations measures have been taken to prevent infection-carrying flies having access to food or food-materials. One case was supposed to have been contracted in hospital from eating of food smuggled in by the sweeper who handled the excreta of the enteric fever patients. At Peshawar some cases were attributed to the eating of dirty water cresses. Bernardmyo is said never yet to have *originated* a case of enteric fever;* and the comparative immunity of Belgam is explained by the barracks standing on high ground, and by the water supply being above the reach of contamination. In the case of other stations where enteric fever was absent, rare, or less, the only explanations offered are the possession of a good water supply, and the taking of pains to guard and disinfect the water and milk. Incineration of the enteric stools is reported to have been practised at Chakrata, Peshawar (from October), and Murree. Out of the 1,795 cases of enteric fever which occurred throughout the army of India in 1896, over 34 (the number in some cases being given only as "several") are noticed as having declared themselves among patients in hospital or among attendants. Out of these over 14 were in hospital for venereal diseases, 13 were in hospital for other diseases, and 7 were attendants on enteric fever cases. A second attack of enteric fever was the lot of a man at Bangalore, and a fatal second attack of a man at Dagshai. In a fatal case at Dum-Dum there was a single abscess of the liver, and in a fatal case at Lucknow there was multiple abscess formation.

Medical officers have reported on outbreaks in the case of which the drinking water was suspected, or was said to contain the enteric bacillus; of the measures considered to have been effectual in preventing or checking the disease; and, especially, of the results obtained by boiling the drinking water, or by adding to it potassium permanganate or other chemicals. The instructions issued for the general adoption of such measures have been mentioned above; and, as far as can be judged, they seem to have been carried out with some thoroughness. It is to be hoped, however, that future results will be more striking than those of 1896. Not only are the reports of medical officers somewhat disappointing, but the reduction in the admission-rate of India for enteric fever was only 0·8 per 1,000 strength, 75 cases fewer. And no difference in the carrying out of the prophylaxis, such as earlier beginning or greater care, can be made out from the reports as a reason why the Punjab command should have had a great reduction, the Bombay

* There were 10 admissions in the three years 1889-91.

and Madras commands a greater increase, the Bengal command the slightest possible decrease.

Commands.	Year.	Enteric Fever.		
		Admissions.	Ratio per 1,000 of strength.	Difference.
Bengal	1895	674	30·3	− 0·1
	1896	679	30·2	
Punjab	1895	770	39·0	− 13·1
	1896	488	25·9	
Madras	1895	171	12·7	+ 4·1
	1896	227	16·8	
Bombay	1895	255	16·3	+ 9·2
	1896	401	25·5	
India	1895	1,870	26·3	− 0·8
	1896	1,795	25·5	

Enteric Fever in 1896.—There was a decrease of both morbidity and mortality from enteric fever in 1896. As compared with the corresponding ratios of 1895, the admission and death ratios fell respectively by 0·8 and 0·41 per 1,000 of strength. There were 1,795 admissions and 445 deaths, against 1,870 and 477 in 1895. The average number of men constantly sick from enteric fever was 260, and the average duration of a case was 53 days. The total loss of service due to disease was about 95,109 days.

Fever Mortality.—The following table shows an increase in total fever mortality, which may be ascribed to the greater youthfulness and less average length of service of the soldiers of to-day :—

	1870–79.			1881–90.†			1895.			1896.		
	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.
Army of India	2·03	1·42	3·45	3·79	·70	4·49	6·72	·59	7·31	6·31	·50	6·81

* Intermittent, remittent, and simple continued fevers.

† Excluding troops on active service in Burma during 1885 to 1887.

It shows in the years 1895 and 1896, as compared with the decennia, an increase of mortality from enteric fever, accompanied by a decrease in mortality from the other fevers, which is probably partly due to increased susceptibility to enteric fever on the part of the army from youth and recent arrival, and partly to the increasing frequency with which the diagnosis of enteric fever has been made.

The following table shows enteric fever in the geographical groups in the decennium 1886–95 and in the last two years :—

Admissions per 1,000.

Period.	Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalayan.	North-Western Frontier, Indus Valley, and North-Western Rajputana.	South-Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Convalescent Depôts and Sanitaria.
	I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII*a*.	XII*b*.
1886–95 ...	5·7	5·5	7·7	27·7	25·4	15·6	23·9	17·0	5·8	12·1	25·1	13·9
1895	8·9	4·9	11·0	37·8	25·5	27·8	22·8	21·7	9·6	10·3	27·0	19·5
1896	13·0	4·5	18·3	40·0	19·8	23·8	30·4	23·1	17·4	16·0	47·2	10·3

It shows that Groups V., VI., VIII., and XII*a*. especially, are apt to have high ratios of admission from enteric fever, and Groups I., II., IV., and X. low ratios. It also shows at a glance how the groups compare with each other in 1896, and how 1896 compares with 1895 or with the decennium. Group XII*a*. had the highest ratio of 1896, and Group V. the next highest, and in the same groups also the percentage of enteric fever in total admissions was greatest.

The distribution of enteric fever throughout the year by stations and months may be studied in Table VIII. But the following shows those garrisons which had an average strength of over 1,000 in 1896, with the decennial ratios for reference :—

Stations.	1896.		Decennium, 1882–91.	
	Admission-rate.	Death-rate.	Admission-rate.	Death-rate.
Allahabad*	87·2	27·20	19·3	5·17

* Including Fort Allahabad.
† Four Years.

The high position occupied by the decennial admission ratios of Bareilly, Lucknow, Ranikhet, and Sialkot will be observed, and the low position of the ratios of Aden, Calcutta, Bombay, Belgam, and Rangoon.

As certain hill stations have attracted attention of late years by the prevalence in them of enteric fever, and as there is a common belief that enteric fever tends to increase with length of occupation, the following table for hill stations is given, showing death ratios from the earliest year that enteric fever was separately shown in the tables of the Sanitary Commissioner with the Government of India:—

YEARS.	Ranikhet.	Chaubuttia.	Chakrata.	Dagshai.	Solon.	Subathu.	Jutogh.	Cherat.	Murree Hills.
1871 ...	—	—	—	—	—	1·30	—	16·50	—

1896 ...	10·58	—	1·10	14·01	4·78	33·48	8·51	10·12	1·76

In the case of most of those stations bad years have occurred at more or less irregular intervals; but for some time past, in the case of Dagshai, Subathu, and Cherat, the bad years have been very close together. Special investigations have been made into the sanitary conditions of those stations, and generally suspicion has been thrown upon the water supply.

With regard to the relation of mortality from enteric fever to age and length of residence in India, the results confirm those of former years. The ratio of mortality from enteric fever per 1,000 of strength was greatest in the age-period 20–24, and the relative liability of the same period was 46 per cent., that is, the highest; in the same age-period the total number of deaths from enteric fever was 342, and out of a hundred deaths from all causes 57 were from enteric fever; lastly, out of the total number that died at all ages from enteric fever 78 per cent. were between 20 and 24 years of age. Again, the ratio of mortality from enteric fever per 1,000 of strength was highest in the first year of residence, and the liability for the same period was 36 per cent., that is, the highest; in the first year the total number of deaths was 160, and out of 100 deaths 69 were from enteric fever; lastly, out of the total number that died at all periods of residence from enteric fever 36 per cent. were in the first year of Indian residence.

As regards the relations of *admission* from enteric fever to age and length of residence in India, the age-period 20-24 included 53 per cent. of the total strength of the army, and in the same period the liability to fall sick of enteric fever was greatest, 42 per cent. In the succeeding periods the liability gradually declined. The greatest liability to get enteric fever was in the first year of Indian residence, and that thereafter the liability suddenly declined. Since arrivals have increased, and since the percentage in the army of men under 25 years of age and of men with less than five years Indian residence has been gradually mounting, the admission ratio from enteric fever has also been rising. The greater has become the supply of susceptible material, the more the disease has prevailed.

The monthly incidence of enteric fever may be studied in Table VIII. In the period 1886–95 as a whole the chief enteric fever season, though the disease occurred in all months, was the six months April–September, with one maximum in May and another in August.

Year.*	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Ratio per 1,000.
1886–95...	518	418	689	1,427	1,795	1,365	1,441	1,718	1,400	923	745	879	13,318	19·6†
1896 ...	65	75	202	214	160	152	175	214	179	90	92	177	1,795	25·5

* The warning given in paragraph 3 as to the months not being calendar months applies here also.
† Including men on Field Service.

In 1896 the greatest prevalence of enteric fever was in March, April, and August; of simple continued fever in June; and of remittent fever in June and July. Of the larger groups, Gangetic Plain had its maximum in March, Indus Valley in June, the Deccan and the Hills in August, Central India in September, Upper Sub-Himalayan in December.

Respiratory diseases.

Respiratory diseases caused less sickness, but greater mortality, than in the preceding years :—

Of the commands the Punjab had, as usual, the highest admission-rate. As to groups, the greatest prevalence was not, as usual, in the Indus Valley, but in Group VIII., Ahmedabad and Nasirabad having had particularly high ratios. The medical officer at Nasirabad says that respiratory diseases are attributable in many cases to the carelessness of the men in coming into the bungalows very hot and sitting behind wet tatties. He adds that the changes of temperature at this station are sometimes very sudden, and so apt to cause bronchial affections.

Probably in connexion with the prevalence of influenza, the admission-rate from pneumonia rose to 5·2 from 4·4, and the death-rate also increased. Upper Sub-Himalayan and Indus Valley were, as usual, the two groups in which pneumonia was most prevalent, but in 1896 the former had a higher ratio than the latter, which is uncommon. Bareilly and Meean Meer had the highest ratios in the Upper Sub-Himalayan group. In the same two groups the percentage of pneumonia to total admissions was also greatest. On page 68 will be found a table showing the relation of pneumonia to influenza year by year, and also of the pneumonia of European troops to that of native troops and prisoners. Most cases occurred in the cold weather, and especially in January, February, and March; January and February having been the minimum months for dysentery, and January and March the maximum months for influenza. The stations with the greatest number of deaths were, in order, Rawalpindi, Peshawar, and Umballa; and their ratios stood in the same order. The medical officer at Rawalpindi says that the pneumonia was very severe and rapidly fatal in the winter months, when the cold was very intense and penetrating; and the medical officer at Peshawar that nearly all the cases occurred in January and the early part of February, when the disease was prevalent and severe among the native population.

The number of European soldiers constantly sick from pneumonia was about 35, and the average duration of a case 35 days against 27. There were no deaths from pneumonia among the troops marching.

Dysentery and diarrhœa.

The admission and death rates from dysentery and diarrhœa fell considerably. This is presumably due to the absence of field service, as well as to the dry and non-malarious character of the year.

Period.	Dysentery.		Diarrhœa.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	30	·73	32	·06
1895	35	1·04	24	·07
1896	26	·67	20	·01

Dysentery was most prevalent in the Madras command and in the Bengal-Orissa group. The same command and group had the highest percentage of dysentery in total cases, as may be seen in the Tables on pages 45 and 47. It is usual for that geographical group to have a high dysentery ratio. Dysentery was most prevalent in September, July, and December, and least so in January and February; of the stations, Secunderabad had the most cases; and Poonamallee Depôt, Pachmarhi Sanitarium, and Barrackpore had the highest ratios.

At the end of a long and careful paper on what is known of the causation of dysentery, Janowski of Warsaw thus sums up:—

"Dysentery is etiologically not a single disease, and is apparently not caused by the action of a "single parasite, but by the combined action of several varieties. From the data offered by the "literature of the subject up to date one may conclude that the cause of dysentery is some association "of bacteria. But one of its forms differs clinically and anatomically from the others: the so-called "tropical dysentery is apparently produced by the association of a certain species of amœba with "bacteria."

Kartulis writes also on the same subject.

In India R. Ross has found amœbæ in some cases both acute and chronic. It seems probable that acute dysentery proper and chronic dysentery in continuation of an acute attack may be of amœbic origin; whereas some of the milder forms, whether acute or chronic, which are more of the nature of intestinal catarrh with follicular inflammation and ulceration, may be caused by bacteria. The presence in the intestine of a very virulent form of the *bacillus coli*, which has been named the *bacillus coli dysentericus*, and many other points relating to the causation of dysentery, have been noticed by recent writers.

Hepatitis and absces of the liver.

Though the admission-rate from hepatitis (including abscess of the liver) rose from 19 to 23 per 1,000 of average strength, the rise was confined to the milder forms, and the death-rate fell from 1·45 to 1·25 per 1,000.

Venereal disease.

From venereal disease the admission-rate for India was 511·6, against 522·3 in the previous year. There were 3,162·43, against 3,164·84, men constantly sick in hospital from venereal disease, equivalent to over three regiments. The average stay of a case of venereal disease in hospital was 32·10 days, against 31·49, and the total loss of service was about 1,157,449 days, against about 1,555,167, men on field service being excluded from the calculation. There were 14 deaths and 479 invalidings directly due to venereal disease, against 15 and 353. The highest ratios were at Ahmedabad, Nowgong, and Shahjahanpur; and the greatest increase of ratio, increases of more than 150 per thousand of strength, were at Shahjahanpur and Saugor in the Bengal command; at Subathu in the Punjab command; at Bhamo and Madras in the Madras command; and at Taragarh (strength under 100), Ahmedabad, Nasirabad, Neemuch, Hyderabad, Sitabaldi (strength under 100), Deolali, and Purandhur in the Bombay command. The total venereal ratios of the commands may be compared in the Table on page 45: as in the previous year, the Bengal command had the highest ratio, and the Punjab the lowest. Only in the Bombay command was there an increase of venereal disease. The chief decrease was in the Punjab, and the decrease in the Bengal command was not much less, while the decrease in Madras was comparatively slight. In 46 stations, against 34, the admission-rate from secondary syphilis was over 100 per 1,000 of strength, the highest ratios being those of Poonamallee Depôt, as in 1895, Taragarh (strength under 100), Purandhur, Khandalla Depôt (strength under 100), as in 1895, Deolali Depôt, Ahmedabad, Chaubuttia, as in 1895; and in 22 other stations, against 28, it was over 75 per 1,000. In 1896 the Bengal command had the highest ratio for primary syphilis *plus* ulcer of the penis, and for gonorrhœa; and the Madras command, as usual, the highest ratio for secondary syphilis. For India the ratio of primary syphilis *plus* ulcer of the penis diminished by 12·6, and the ratio of gonorrhœa by 11·0, while the ratio for secondary syphilis increased by 12·8 per 1,000 of strength, the net result being a decrease in total venereal disease, as already mentioned.

In the Bengal command the Rohilkhand district had the highest ratio for syphilis, and the Bandelkhand district the highest for gonorrhœa; while in the Madras command the Madras district had the highest ratio for secondary syphilis.

At Calcutta, Fyzabad, Cawnpore, Chaubuttia, Cherat, Poonamallee, and Belgam the treatment of men as out-patients by hypodermic injection or otherwise appears to have restricted the number admitted and constantly sick. Increase of one or more forms of venereal disease at Meerut, Satara, Purandhur, Mount Abu, and Aden was said to have been largely due to the arrival of men who had contracted the disease elsewhere. Increase at Kurrachee was ascribed to the greater vigour of the men from the diminution of malaria

in 1896. Virulent disease is said to have been caused at Kuldunnah by a number of diseased women who followed the troops up from the plains and settled near the barracks. One reason for the prevalence of the disease at Pallavaram is said to be that the men have little to do, and can easily take a run into Madras City. The decrease at Poona was credited to the fact of the bazars having been placed out of bounds from April to September on account first of small-pox and then of cholera.

To show that the venereal ratios do not err on the side of excess, it may be mentioned, besides what has already been stated regarding out-patient treatment, that the medical officers of Lucknow, Fyzabad, Fatehgarh, Bareilly, Jhansi, Cherat, Belgam, Bellary, and Kirkee are inclined to believe that the cases of inflammation of the inguinal glands returned by them as non-venereal were in reality probably of venereal origin, though definite proof was wanting.

Statistics show clearly how the arrival, year by year, of fresh batches of young unmarried men under the short service system has been accompanied by an increase of venereal disease. Since 1878 the number of fresh troops arriving in the country has, as a rule, been much greater than before. The gradual rise in the percentage of men under 25 years of age in the army, and of men under 5 years' Indian service has been pretty uniform, as has been the well-marked decline in the number of married men ; and the same .may be said of the gradual rise in the venereal ratio. As youth and recent arrival have become more common in the army, venereal disease and enteric fever have, not unnaturally, increased in frequency of occurrence.

The following table shows the admission-rate for venereal disease as far back as the records for India as a whole permit. The heading " primary syphilis " includes the local sore throughout :—

Venereal Diseases in the Army of India.

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.
1872	61·2	22·4	179·0	1885	122·1	28·7	342·7*
1873	53·4	20·4	166·7	1886	157·9	33·3	389·5*
1874	68·3	25·2	192·7	1887	142·1	29·4	361·2*
1875	67·1	25·1	205·1	1888	142·1	32·4	370·6
1876	59·8	23·9	189·9	1889	225·1	51·2	481·5

1884	90·2	24·4	293·9				

* Including troops on active service in Burma.

The figures in the above table show a more or less continuous rise, especially since the end of 1884 ; and the secondary syphilis ratio of 1896 is the highest on record. This is a condition of things which is sure to tell, when the men have to go on field service.

The following table, the data for which were specially obtained by the Principal Medical Officer, Her Majesty's Forces in India, from the medical officers concerned, and which excludes men on field service or on the march, distinguishes between the number of admissions and the number of individual men admitted into hospital for venereal disease in *1895* :—

Average annual strength.	Number of men admitted once only.	Number of men admitted twice but not oftener.	Number of men admitted three times but not oftener.	Number of men admitted four times or oftener.	Total number of men admitted.	Total admissions.
66,954	21,137	4,620	1,235	496	27,488	36,190

The number of individuals treated was about three-fourths the number of admissions ; and the former were in the proportion of 410·6 per 1,000 of strength, the latter of 540·5.

For every 10 men in the army affected by venereal disease there were about 14 free from the same ; or, in other words, in every 1,000 men 411 men were diseased and 589 exempt.

As ague and venereal diseases are the chief causes of admission, and enteric fever and hepatitis the chief causes of death in the European army of India, a table is here given to compare the last two lustres in the case of each of the stations that had in 1896 a strength of over 1,000 :— Past and present sickness and mortality.

Stations.		Admitted per 1,000.		Died per 1,000.		Stations.		Admitted per 1,000.		Died per 1,000.	
		Ague.	Venereal disease.	Enteric fever.	Hepatitis and abscess of liver.			Ague.	Venereal disease.	Enteric fever.	Hepatitis and abscess of liver.

	1891–95	983·7	239·7	10·09	·97		1891–95	819·0	306·7	1·69	1·06

There are 26 stations in the above list ; and 15 of them show an increase in ague, specially Ferozepore, Sialkot, Peshawar, Mooltan, Kurrachee, Secunderabad, and Aden. The prevalence of fever at Aden is under investigation. The venereal ratio of 19 stations rose, the greatest rise being at Ranikhet. The mortality from enteric fever was greater in 11 stations, and less in 15, the greatest increase taking place at Lucknow, Meerut, Umballa, Rawalpindi, Peshawar, and Poona, and the greatest decrease at Ranikhet and Sialkot. Hepatitis mortality fell at 19 stations, and rose at only 7 ; the greatest rise was at Agra, Poona, and Bombay, but no less than 9 stations showed large decrease. The general result over the whole is increase of sickness from ague and venereal disease, diminished mortality from enteric fever and hepatitis.

In the whole army of India 1,966 men were invalided, or 27·89 per 1,000 of strength, against 1,663 and 23·41 in the preceding year. The ratio for the decennium 1886–95 was 24·34. The proportion of invalids to strength was lowest in the Bombay command, highest in the Madras command. Invaliding.

—	1892.	1893.	1894.	1895.	1896.
India	40	39	39	33	39

Thirty-nine per cent. of the total number invalided were discharged as unfit for further service. The above table shows that this percentage was not at all out of the common.

Diseases causing Invaliding.—The following table shows the diseases which accounted for not less than 1 per 1,000 of strength :—

Invaliding Ratios per 1,000 of Strength.	—
Syphilis and gonorrhœa	6·77
Debility	2·61
Tubercle of the lungs	2·06
Malarial fevers	1·93
Dysentery	1·15
Valvular disease of the heart	1·08

The ratio of invaliding from mental diseases increased, having been unusually low in the preceding year. There were 39 cases of melancholia, 27 of dementia, and 21 of mania.

Ratios per 1,000 of Strength.	—
1886–95	1·19
1895	·77
1896	1·05

Invaliding according to Age and Indian Service.—The percentage of men who were invalided while under 25 years of age to the whole number invalided was (*f*) 62, against 66 in 1895. The percentage of men under 25 in the strength of the army was 56, against 55.

Of the total number of men invalided 40 per cent. were of less than two years' service, and 85 per cent. were of less than five years' service. With this is to be considered the fact that 82 per cent. of all the men in the strength of the army were of less than five years' service.

With regard to individual diseases the highest invaliding ratio per 1,000 of strength from venereal disease was in the age-period 20–24, and the relative liability for that period was 46 per cent. ; the actual number invalided for venereal disease in the same age-period was 306 ; of 100 invalidings in the same age-period 26 were due to venereal disease, a proportion only approached by that of the immediately succeeding age-period ; and of the total number invalided for venereal diseases at all ages 64 per cent. were in that same age-period. The residence-period 1–3 years, and especially the first half of the period, had the greatest proportion of invaliding for venereal disease ; whereas in 1895 it was more particularly the second half of the period 2–4 years which was so distinguished.

Statistics of officers.

The vital statistics of officers show that the death-rate for *all* in the British army was 14·18, and that for the Indian army 10·76. Both these ratios were higher than in the preceding year, the increase being from pneumonia, cholera, and circulatory diseases. The number of deaths from enteric fever among both British and Indian officers was exactly the same as in 1895. Enteric fever caused more deaths among the British than among the Indian officers, apparently because Indian officers have to serve first with British regiments, and it is known that youthful and newly-arrived men are more liable to take the disease than others.

The greatest numbers of cases of enteric fever at individual stations were 8 at Quetta, 6 at Poona, 3 at Meerut, and 3 at Kirkee. No special remarks are made on these cases, except as follows in the case of Meerut :—

" As to the R.A. officers, a bacteriological examination of the water supply of the lines, and also the " milk from the R.A. dairy was made at Agra, but no enteric microbe was detected. And it would " appear that the mess of the R.A. obtained their milk from the bazar, which probably may have " been the medium through which the microbe was conveyed. Since then this source of supply has " ceased."

Sickness and mortality among women rose; and it may be noted that the mortality of 1895 was already higher than that of 1894 :— Statistics of women.

Period.	Average annual strength.	Admission-rate per 1,000.	Constantly sick-rate per 1,000.	Death-rate per 1,000.
1886–95	31,881	815·2	32·1	17·00
1895	3,194	804·3	35·2	17·85
1896	3,254	807·0	37·4	18·44

The chief causes of admission were debility, ague, and the diseases peculiar to women. Among the diseases which caused increased admission were small-pox, influenza, and female diseases; while from enteric fever, malarial fevers, and bowel complaints admission was lessened. Debility caused nearly 35 per cent. of the total sickness, and ague 16 per cent.

The chief causes of death were enteric fever, child-birth and abortion, and tubercle of the lungs. Among the diseases which gave increased mortality were enteric fever and ague. Mortality from remittent fever, child-birth and abortion, cholera, and pneumonia was diminished. Enteric fever caused 18 per cent. of the total deaths, puerperal affections 8 per cent., and tubercle of the lungs 7 per cent. There was no cholera among the women.

That sickness among children in 1896 fell, while mortality rose, is seen in the following table :— Statistics of children.

Period.	Average annual strength.	Admission-rate per 1,000	Constantly sick-rate per 1,000.	Death-rate per 1,000.
1886–95	59,695	581·8	22·7	46·72
1895	5,699	598·5	26·2	41·24
1896	5,790	573·6	24·9	45·60

The chief causes of admission were ague and respiratory diseases. Among the diseases with raised admission-rates were small-pox, measles, and enteric fever; while admission from influenza, cholera, malarial fevers, respiratory diseases, and bowel complaints was lessened. Ague caused 16 per cent. of the total sickness, respiratory diseases 13 per cent., and measles and diarrhœa each 7 per cent.

The chief causes of death were convulsions, debility (including immaturity at birth), diarrhœa, and teething. Among the diseases from which there was increased mortality were small-pox, diphtheria, enteric fever, convulsions, respiratory diseases, teething, and dysentery. Mortality from remittent fever, cholera, diarrhœa, and debility was diminished. Convulsions caused 14 per cent. of the total deaths, debility nearly 14 per cent., diarrhœa over 12 per cent., and teething nearly 12 per cent. There were no cases of cholera among children in 1896.

Native Troops.

Sickness and mortality in 1896.

Owing, no doubt, to the dry and non-malarious character of the year, there was less sickness and mortality than in 1895, even though influenza and cholera were more prevalent :—

Year.	Average strength.	Ratio per 1,000. Admissions into hospital.	Constantly sick.	Deaths from: Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.	Mortality, including absent deaths.
1886–95 ...	123,302	976	34	1·32	1·34	3·02	·78	12·43	16·72
1895	129,655	794	30	·41	1·20	4·20	·53	11·60	15·71
1896	128,286	763	29	·69	1·07	3·14	·42	10·20	12·57

The chief cause of admission was ague. Among the diseases with raised admission-rates were influenza, cholera, small-pox, and venereal disease. Among those with lessened rates were enteric fever, ague, remittent fever, simple continued fever, pneumonia, other respiratory diseases, dysentery, and diarrhœa. Ague caused 36 per cent. of the total admissions.

The chief causes of death were pneumonia and remittent fever. Among the diseases which caused increased mortality were cholera and small-pox. Among those from which mortality was lessened were respiratory diseases, bowel complaints, and fevers. Pneumonia caused 31 per cent. of the total deaths, and remittent fever between 10 and 11 per cent.

The total number invalided for discharge was 1,437, and the chief causes of invaliding were debility, venereal diseases, and respiratory diseases.

If the following table be compared with that at page 45 it will be seen that the Native soldier suffered less from influenza, small-pox, enteric fever, simple continued fever, tubercle of the lungs, diarrhœa, hepatic affections, and venereal diseases, and more from ague, remittent fever, respiratory diseases, dysentery, and scurvy than his European comrade. These relations are usual, except with regard to influenza and small-pox.

All Causes	8·52	14·37	8·04	8·82	10·47	7·03	10·20

Of the commands the Punjab was the most unhealthy, but it was more healthy than in the previous year. Its death ratios from cholera, small-pox, and hepatic abscess were raised, while those from enteric fever, ague, remittent fever, pneumonia, other respiratory diseases, dysentery, diarrhœa, and debility were lowered. The Punjab had the highest death-rate, Madras the highest constantly sick-rate, and Bombay the highest admission-rate. The highest ratios of mortality from remittent fever, pneumonia, and other respiratory diseases, and the lowest from cholera, were in the Punjab; the highest from ague, dysentery, and debility, and the lowest from remittent fever, pneumonia, and other respiratory diseases, in Madras; the highest from small-pox, diarrhœa, and hepatic abscess in Bombay.

The following table shows the statistics of all the native troops serving in Burma and the Andamans. Of these troops in 1896 about 98 per cent. belonged to the Madras army:—

Year.	Average annual strength present.	Ratio per 1,000.						
		Admissions into hospital.	Constantly sick.	Deaths from				
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.
1891	11,401	1,676	76	1·75	2·98	1·84	4·03	36·31
1892	11,333	1,349	57	2·29	2·29	2·29	3·09	29·12
1893	10,326	1,092	48	·87	1·45	2·42	1·36	19·85
1894	10,500	809	35	1·43	·95	1·14	1·43	13·90
1895	9,952	827	37	·80	·50	·80	·80	10·55
1896	9,605	830	38	—	·94	·73	1·35	9·58

The table shows that the death-rate has been reduced year by year. Sickness was not high, though higher than in the previous year. A comparison of the health of the troops

in the Burma Coast group of stations with that of the troops in the Burma Inland group may be made by the use of the following table :—

Ratios of Geographical Groups.

	Ratio per 1,000 of the Average Strength.												
	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII.

In the above table it may be seen that Burma Coast had the lowest admission ratios from malarial fevers and respiratory diseases; Burma Inland the highest from ague; Assam the highest from cholera, enteric fever, dysentery, diarrhœa, and venereal disease; Bengal-Orissa the highest from simple continued fever; Indus Valley the highest from pneumonia; Western Coast the highest from remittent fever and hepatitic affections; Southern India the highest from smallpox, and the lowest from dysentery; and the Hills the highest from influenza and from respiratory diseases other than pneumonia. The presence of enteric fever and the prevalence of venereal disease in Assam is due to the number of Gurkha troops there.

Of the large stations throughout India with a strength of not less than 1,000 the following returned the highest death-rates:—Manipur, 37·66; Nowshera, 37·77; Peshawar, 21·34; Kohat, 19·25; Dera Ismail Khan, 19·19.

The principal cause of death at Manipur was cholera, at the four frontier stations pneumonia.

Attention having been directed to the health statistics of India, of the commands, of the geographical groups, of stations, and of regiments, it will be convenient now to consider some of the chief diseases. Influenza increased, there having been 1,369 cases, 10·7 per 1,000 of strength, against 910 cases, 7·0 per 1,000 of strength, in the preceding year. There was more influenza in 1896 than there had been since 1892. The geographical groups affected both in 1895 and in 1896 were IV., V., VI., VII., VIII., IX., XI., XII.; II. and III. were newly attacked in 1896; X. escaped in both years, while I. has had no cases since 1892. In proportion to strength the Hills was, as in the previous year, the group most severely affected; whilst the greatest number of cases occurred, as in 1895, in the Hills and Indus Valley. The following table shows the monthly progress of of the disease since its beginning in 1890. The maximum month varied from year to Principal diseases: Influenza.

year, but over the period as a whole most cases occurred in April and March, and fewest in October and September :—

Years.	Number of Admissions into Hospital each month.												Total.	Admitted per 1,000 of Strength.	Died per 1,000 of Strength.
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.			
1890 ...	1	8	2,460	5,118	492	82	55	—	—	—	1	—	8,217	64·3	·41
1891 ...	—	—	1	—	105	259	123	106	51	22	17	215	899	7·0	·09
1892 ...	681	371	511	149	40	5	5	7	—	1	7	18	1,795	14·1	·15
1893 ...	8	28	65	99	95	13	9	7	—	3	53	404	784	6·2	·20
1894 ...	159	203	232	384	143	11	5	—	1	1	5	11	1,155	9·0	·16
1895 ...	26	28	53	76	110	25	60	57	19	17	31	408	910	7·0	·08
1896 ...	372	196	397	35	22	11	33	57	53	39	82	72	1,369	10·7	·30
Total	1,247	834	3,719	5,861	1,007	406	290	234	124	83	196	1,128	15,129	16·9	·20

The greatest number of cases occurred at Quetta, Dharmsala, and Edwardesabad. At the first named station the disease was present during the last six months of the year, while in the other two it was confined to the first four and first two months of the year respectively. The following table shews that in 1896, as in the previous year, the native troops were somewhat less severely affected than the European troops, much less severely than the prisoners :—

Years.	Per 1,000 of Average Strength.											
	Influenza.						Pneumonia.					
	European Troops.		Native Troops.		Prisoners.		European Troops.		Native Troops.		Prisoners.	
	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.
1890	33·4	·03	64·3	·41	78·6	·67	4·6	·90	16·7	3·96	18·5	5·71
1891	5·5	·04	7·0	·09	19·0	·29	2·6	·54	11·6	2·53	17·0	4·87
1892	12·7	·01	14·1	·15	56·7	1·26	3·5	·62	13·6	3·26	18·4	5·56
1893	·3	—	6·2	·20	6·4	·09	3·4	·70	12·3	2·75	15·9	3·95
1894	3·4	·01	9·0	·16	41·0	·43	3·7	·75	12·9	2·87	15·4	4·31
1895	7·8	·03	7·0	·08	20·3	·15	4·4	·51	17·5	4·20	16·4	4·00
1896	11·5	·11	10·7	·30	37·6	·60	5·2	·64	15·3	3·14	19·1	4·34

It also shows the relation of the pneumonia death-rate year by year to the admission-rate from influenza. In comparing 1896 with 1895 from this table it must be remembered that the unusual height of the death-rate from pneumonia in 1895 was the result of field service in Waziristan and Chitral.

Cholera.

There were 132 cases of cholera with 88 deaths, against 75 cases with 53 deaths in the preceding year. The admission-rate per 1,000 was 1·0, against 0·6, and the death-rate 0·69, against 0·41. Cases occurred in every month except January and February, the maximum months being June–August. The greatest number of cases occurred in Assam and the Deccan. Among stations Manipur had most cases, namely, 37, the greatest number at any other station being ten. The regiment affected at Manipur was the 44th Gurkha Rifles, the explosion of the disease being attributed to pollution of the river by the dejecta of cases in the civil population.

The following table gives information regarding the cholera of the period 1886–95 :—

—	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Ratio per 1,000. Admitted	Ratio per 1,000. Died.
European troops	6	4	22	76	126	67	285	336	177	91	65	25	1,280	1·9	1·33
Native troops ...	72	152	52	305	401	220	490	313	227	140	169	112	2,653	2·2	1·32
Prisoners ..	263	83	241	437	352	334	1,115	873	269	146	311	184	4,608	4·8	2·75

In the period as a whole the European troops suffered less than the native troops, and both less than the prisoners. In each of the 10 years, except 1890, the prisoners were most affected, and in a slight majority of years the European troops least. The table also shows that August and July were the maximum months for European troops, July and May for native troops, and July and August for prisoners.

Small pox.

There were 148 cases of small-pox with 13 deaths, against 71 cases with 8 deaths in the preceding year. The admission ratio per 1,000 was 1·2, against 0·5, and the death ratio 0·10, against 0·06.

Fevers.

To ague was due 36 per cent. of the sickness of the native army. The admission-rate from ague fell in 1896. Statistics show that in 1896, as in 1895, Burma Inland was the most malarious group, and Burma Coast the least malarious ; and the most malarious months were September and October, and the least malarious month February. Remittent fever caused over 10 per cent. of the total deaths, and prevailed most in September and October. The proportion of cases returned as simple continued fever is much lower in the native army than in the European ; but it is pretty certain that many cases, which in the latter would be so returned, are in the former called ague. The simple continued fever of the native army was most prevalent in April–June, and in the same period the greatest number of enteric fever cases were diagnosed.

Several medical officers mention the benefit derived by the regiments in their medical charge from the prophylactic issue of quinine and other anti-periodics ; and there is no doubt that the regular issue of the same is a practice which ought to be strongly encouraged throughout the army. The medical officer of the 27th Bombay Infantry at Hyderabad (Sind) states that ague was much increased by the water having been allowed to run into the canals and channels in and around Hyderabad this year.

The ratio of admission from enteric fever in the native army in 1896 was 0·1 per 1,000 of strength, and the death-rate 0·04, against 0·2 and 0·07 in the previous year. The corresponding decennial ratios of 1886–95 are 0·2 and 0·08. The following table shows that the ratios for European troops are very unlike those for native troops and prisoners :—

—	1886–95. Admissions.	1886–95. Deaths.	1896. Admissions.	1896. Deaths.
European troops	19·6	5·28	25·5	6·31
Native troops	·2	·08	·1	·04
Jail population	·3	·12	·2	·05

Post-mortems are rarely obtainable in the case of native soldiers ; but among prisoners nearly every fatal case of disease is subjected to *post-mortem* examination. Under these circumstances, as has been repeatedly pointed out, the fact that the ratios of prisoners and sepoys for a ten year period are almost identical appears to show that the native troops really suffer less than the European ; though it does not show that there may not be more cases of enteric fever among both native troops and prisoners than are at present diagnosed during life or after death. Again, the following table shows that the total fever mortality

in the two armies is not the same in amount, which indicates that the difference is not altogether a mere matter of diagnosis :—

Causes of Death.	Died per 1,000 of Average Strength.		Relative Liability in Percentages.			Percentage in Deaths from all causes.	
	European Troops.	Native Troops.	European Troops.	Native Troops.	Total = 100	European Troops.	Native Troops.
Ague	·10	·48	17	83	100	·7	4·7
Remittent fever	·40	1·07	27	73	100	2·7	10·5
Simple continued fever	—	·03	—	100	100	—	·3
Enteric fever	6·31	·04	99	1	100	42·5	·4
Total	6·81	1·61	81	19	100	45·9	15·9

The total fever mortality among the native troops in 1896 was to the total fever mortality among the European troops as 1 : 4·2. For the period 1886–95 the corresponding ratio was 1 : 2·6 and for 1895 it was 1 : 3·9. Again, among the European troops, 46 per cent. of all deaths in 1896 were from fevers; only 16 per cent. among native troops. As the death-rate of European troops from enteric fever is nearly four times as great as that of native troops from all kinds of fever, it appears, whatever may be the nature of the remittent and continued fevers from which native soldiers die, that native soldiers and prisoners are less liable to enteric fever than European soldiers are.

The question of the immunity, or apparent immunity, of natives of India as regards enteric fever, has been frequently discussed in former reports. At page 62 of the report for 1895, and at page 33 of that for 1890, was noticed the suggestion that the modern British soldier has become very liable to contract the disease in badly sanitated India, because in now purer England he has not had the opportunity of going through the disease at an earlier age. The same view had since been led up to in a different way by Surgeon-Major S. F. Freyer, Army Medical Staff, who by the use of Widal's serum test thinks he has discovered that nearly all natives of India above the age of early childhood have already passed through the disease. That they have may or may not be true, and it has been mentioned in these reports that some medical officers in India believe it to be true; but Surgeon-Major Freyer's intended proof cannot be accepted without further confirmation, especially as his own paper shows that he did not realise the necessity of minute care and strictness in the experiments. His results were criticised from this point of view by Mr. A. M. Gossage, and the references given here will show that the latter was justified in his criticism. The danger of error arises from the fact that the reaction is not only qualitative but also a quantitative one, there being a small amount of agglutinative power in normal sera, so that certain limits of dilution and time have to be observed. Again, cultivations which are not quite fresh often begin to a certain degree to clump spontaneously, and this danger has to be guarded against by microscopic examination of the culture before use. It has also been found that the composition, reaction, and temperature of the medium in which the cultivation is made have something to do with the readiness with which agglutination may be displayed. Therefore, before undertaking the experimental diagnosis, it is necessary to make sure of the genuineness, purity, freshness, activity, virulence, and freedom from clumps of the culture; and thereafter to find out the relation, within the limits of the intended dilution and time-allowance, of these genuine bacilli to a serum known to be normal. It is evident from what has been said that an inexperienced experimenter is in most danger of getting an erroneous *positive* result; and that the test is not one to be trifled with by the general practitioner, but to be entrusted only to the hands of the bacteriological expert, who realises the sources of fallacy to be avoided. As Professor Sheridan Delépine says :—

"The simplicity of the method may induce clinicians to use it at the bedside. I doubt whether "this would be a wise application. The whole method depends for its success on the purity "of the cultures, on their being in an active state of growth, on their being free from clumps, "and on the observations being made by men to whom bacteriological observations are so familiar as "to prevent those many slight sources of inaccuracy which attend experiments made by those who

" are not in constant training. The very simplicity of the method is for these reasons a source of " danger, and I should not be surprised if the generalisation of the method were attended by disbelief " in its value, if it is to be used indiscriminately by anybody who happens to possess a tube labelled " 'typhoid bacillus' and a platinum loop."

In the whole native army of India 19 cases with 5 deaths were returned as enteric fever, as against 22 cases with 9 deaths in 1895. In only three cases were *post-martems* obtained; and the lesions described support the diagnosis. Regarding the three cases that occurred at Manipur, the medical officer of the 44th Gurkhas says :—

" The three cases occurred soon after each other. They came from different companies; two from " one and one from another. The source of contagion was not traced; probably the river water was " to blame, as it was at the beginning of the rains. There is always a lot of simple continued fever " about that time of the year; and I strongly suspect that at least some of these are cases of enteric " fever in which the diarrhœa is absent or very slight. All are treated as if they were."

Both morbidity and mortality from respiratory diseases were less than in 1895, and were also unusually low :— Respiratory diseases.

Period.	Ratio per 1,000 of Strength.			
	Respiratory Diseases.		Pneumonia.	
	Admissions.	Deaths.	Admissions.	Deaths.
1886–95	50	3·75	13	3·02
1895	53	4·87	18	4·20
1896	43	3·72	15	3·14

Respiratory diseases are the chief cause of death in the native army, and in 1896 over 36 per cent. of all deaths were due to them. For respiratory diseases other than pneumonia, the highest admission ratios were those of the Hills, Indus Valley, Bengal-Orissa, and Burma Inland, and the lowest that of Burma Coast. Of commands the Punjab has the highest death-rate, and Madras the lowest.

The admission and death ratios from pneumonia, as may be seen from the table given in the preceding paragraph, fell considerably; but were still, nevertheless, above the decennial ratios. The ratios of 1895 had been unusually high owing to the exposure endured by the regiments on active service in Waziristan and Chitral. Again, the second table on page 68 shows how far the yearly increase or decrease of influenza has affected the pneumonia death-rate. If the following be compared with the same table, it will be seen that the influenza prevalence, which began in 1890, has caused pneumonia mortalities to run higher :— Pneumonia.

Years.	Ratio per 1,000 of Average Strength.			Years.	Ratio per 1,000 of Average Strength.		
	European Troops.	Native Troops.	Prisoners.		European Troops.	Native Troops.	Prisoners.
1883 ...	·58	3·31	3·98	1887 ...	·54	2·81	4·53
1884 ...	·53	2·33	4·08	1888 ...	·49	2·28	4·36
1885 ...	·75	2·94	4·00	1889 ...	·46	2·66	4·94
1886 ...	·48	2·75	4·22				

The admission and death ratios were, as usual, highest in the Indus Valley, and the percentage of pneumonia to total deaths was there also highest. Both in the Indus Valley and in the Hills pneumonia was most prevalent in the cold months; and the same was the case for India as a whole.

From dysentery, the admission and death rates were considerably lower than in the preceding year. The comparative prevalence and mortality from dysentery in the various Dysentery, diarrhœa.

portions of the army of India may be studied in tables on pages 64, 65 and 66. The highest admission-rates were in the Bengal command, and the Assam group; the highest death-rates in the Madras command, and in the Burma Inland group. The death-rate of native troops from dysentery was to that of European troops as 1 : 1·6; and the percentage of dysentery in total cases of death was 4·1 in the case of native troops, and 4·5 in the case of European troops. Again, the case-mortality of native troops was 1·01 per cent., while that of European troops was 2·38. The admission-rate of native troops, however, was much higher than of European troops, 39·1 to 26·1.

Venereal diseases.

Details regarding venereal diseases in 1896 will be found in the tables on pages 64 and 66. The following table is given to compare with the corresponding one for European troops on page 60 :—

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.
1877	11·5	5·3	26·7	1887	12·6	6·1	27·4
1878	16·3	5·8	37·5	1888	13·5	5·4	31·5
1879	16·5	7·0	37·1	1889	16·6	6·4	38·9
1880	15·0	5·8	33·3	1890	16·0	6·9	41·1
1881	17·9	7·2	39·5	1891	13·6	6·9	37·9
1882	14·7	5·9	34·4	1892	14·1	7·9	39·6
1883	13·0	6·5	31·6	1893	13·3	9·0	36·4
1884	11·0	5·3	27·9	1894	13·8	8·2	32·3
1885	11·2	5·9	30·1	1895	13·1	7·3	31·3
1886	13·7	6·0	28·1	1896	15·5	8·9	37·2

The figures for India are not available for the years before 1877. All the venereal ratios of native troops run at a much lower level than those of European troops; and there is not the same tendency to increase in the ratios of the former as in those of the latter, there having been no change in the native army corresponding to the introduction of the short service system in the European army.

A comparison of the tables on pages 45 and 64 and 65 will show that, leaving Central India, Rajputana, and Hyderabad out of account, the lowest ratios for both European and native troops were those of the Punjab command, and the highest those of the Bengal command. In all the commands the ratios of native troops were much lower than those of European troops.

Whilst among the European troops an average strength of 70,484 gave 36,058 admissions, in the case of the native troops an average strength of 128,286 gave only 4,757 admissions. In other words, there were only 37 admissions for every 1,000 men among native troops, against 512 for every 1,000 men among European troops.

The admission-rate for India was 5·8 per 1,000 more than in 1895. There were 8 deaths and 89 invalidings directly due to venereal disease. Among stations with high ratios, with great increase of ratio, with much secondary syphilis, those occupied by Gurkhas are prominent. Nine more stations than in the previous year had ratios over 20 per 1,000 from secondary syphilis, and 16 more, ratios over 10 per 1,000.

Beri-beri. Dochmius.

All of the 81 cases returned as beri-beri occurred in the Madras command, and of the 13 deaths 6 occurred in Burma and 7 in the peninsular part of the Madras command. In the 20th Madras Infantry at Vizianagram occurred 35 cases with 3 deaths, principally among the Tamil recruits, and in the 17th Madras Infantry at Rangoon 20 cases with 3 deaths. Nothing of importance is contributed as regards etiology, though the medical officer of the latter regiment describes the symptoms and treatment with some care. No cases of sickness or death caused by the *dochmius duodenalis* were reported.

Jails.

Sickness and mortality in 1896.

The year 1896 having been, as already stated, comparatively settled, dry, rainless, and bright, sickness was less than usual, specially sickness due to malaria; but, on the other hand, there was more or less food scarcity, and influenza and cholera were more prevalent.

Year.	Average Annual Strength.	Ratio per 1,000.									
		Admissions into Hospital.	Constantly Sick.	Deaths from							
				Cholera.	Remittent Fever.	Dysentery.	Diarrhœa.	Respiratory Diseases	Phthisis Pulmonalis	Anæmia and Debility.	All causes.
1882–91*	89,642	1,093	38	2·91	1·60	6·84	3·93	5·99†	2·37	2·16	33.61

* Excluding subsidiary jails. † From 1886.

The chief causes of admission to hospital were ague; abcess, ulcer, and boil; dysentery; and diarrhœa. Among the diseases with raised admission-rates were influenza, cholera, small-pox, simple continued fever, tubercle of the lungs, and pneumonia; while the rates from enteric fever, ague, remittent fever, respiratory diseases other than pneumonia, dysentery, diarrhœa, and scurvy were lowered. Ague caused 28 per cent. of the total sickness, and bowel complaints 16 per cent.

The chief causes of death were dysentery, pneumonia, tubercle of the lungs, and diarrhœa. Among the diseases with increased mortality were cholera, tubercle of the lungs, and pneumonia. Among those with lessened mortality were enteric fever, remittent fever, respiratory diseases other than pneumonia, dysentery, diarrhœa, and debility. Dysentery caused 21 per cent. of the total deaths, pneumonia 16 per cent., and tubercle of the lungs 11 per cent.

The following statement shows for each administration, except the Andamans, the proportion of prisoners in 10,000 of the population. Some of the prisoners of each province have been transported to the Andamans, and these are necessarily excluded from the calculations; so that the ratios are all somewhat too low :—

Administrations.	Period.	General Population According to Census of 1891.	Prisoners.		
			Average Number.*	Proportion per 10,000 of Population.	Deaths per 1,000 of Average Strength.*
Burma	1895	7,605,560	13,666	18·0	17·93
	1896		14,460	19·0	18·19

* Excluding subsidiary jails.

† From 1886.

The prisoners of the Central Provinces and of Bombay were more unhealthy than in the previous year, the latter only very slightly so.

In 1896 the two most unhealthy administrations were, in order, the Central Provinces and Assam ; and the three most healthy were, in order, Berar, Madras, and Burma.

As compared with the decennial ratios, cholera mortality was increased only in Bombay and Berar ; dysentery and diarrhœa were nowhere simultaneously increased, nor was diarrhœa increased in any province ; dysentery was increased in the Andamans, Bombay, and especially in the Central Provinces. Mortality from respiratory diseases was increased in the North-Western Provinces and Oudh, Bombay, Berar, the Central Provinces, and Madras ; phthisis mortality rose in Burma, Assam, the North-Western Provinces and

Oudh, the Punjab, Bombay, the Central Provinces, and Madras; and the total mortality increased in Assam, the North-Western Provinces and Oudh, Bombay, Berar, and the Central Provinces.

It will be noticed in the above table that the total mortality of the Punjab jails for 1896 is less than half the corresponding decennial ratio. The contrast between the high mortality ratios of the Central Provinces, Assam, and Bombay, and the low ratios of the Punjab, Burma, and Madras is very striking. The use of prophylactic doses of quinine or cinchonidine, though more extensive than at first, is still not sufficiently general.

The Principal Medical Officer of the Andamans reports, that owing to the large number of convicts employed in building the cellular jail there have been no reclamations in recent years, and fewer men have been employed in the forest work and on unhealthy labour generally; and that this change has operated very favourably on the health of the convicts. With regard to the water-supply he writes:—

"I have frequently noticed the defects in the water-supply, more especially in the dry weather "before the monsoon rains, when nearly all the wells and many of the tanks dry up. It is difficult to "effect any radical change in a country where there are no streams, and where a rocky subsoil prevents "the sinking of deep wells. Considerable improvements have, however, been carried out for the "protection and purification of wells and tanks. A patent boiler has been supplied to all big stations "and hospitals, and the convicts are supplied with water boiled under careful supervision. The "drinking water has been boiled in the Settlement for a good many years; but the patent boiler "invented by Mr. Larymore, and used in the Bengal jails, has a great many advantages, and facilitates "supervision. Convicts do not like boiled water, and will, if they can, evade the orders on the "subject. At large stations under close supervision, like Ross, Viper, Aberdeen, Dundas Point, "and in the local jails, the orders are fairly well carried out; but in the out-stations, where the "supervision depends nearly altogether on convict petty officers, one cannot expect very much "accuracy in details."

"About half the jails in the province of Burma were in a chronic condition of over-"crowding throughout the year." The increase in the total deaths from tubercle of the lungs and respiratory diseases was doubtless influenced thereby. As the Moulmein Central Prison has been persistently unhealthy for the past ten years, the Local Government is of opinion that it should be converted into a district jail, as soon as sufficient accommodation is available elsewhere.

The conclusions arrived at by the Chief Commissioner of Assam as to the causes of the high mortality in 1895 led to the issue of orders in June 1896 restricting the employment of prisoners on extra-mural labour, and providing for the supply of dry and adequate clothing to those employed on such labour on their return to jail. In the predecessor of this report it was pointed out that other causes besides extra-mural labour were probably at work in producing the sickness, and it was suggested that the scales of diet in use were probably defective and insufficient. Steps have been taken to introduce into the larger jails the following measures, and rules are to be drawn up to make them generally applicable in all jails and lock-ups:—A more liberal scale of diet, including a large quantity of good vegetables and an extra meal in the early morning for prisoners employed extra-murally; the discontinuance of the use of new rice; and the more extended prophylactic use of iron and quinine.

The results of the preventive issue of anti-periodics in Bengal are described in paragraph 85*. Among other works for improving the supply of drinking water to the prisoners, it may be noted that the Pasteur-Chamberland filter has been installed in the jails at Motihari, Chaibassa, Bankipur, Jalpaiguri, Bogra, Dinajpur, and Rangpur. The Hazaribagh Central Prison, the "infirmary jail" of the province had a comparatively small mortality, owing to the systematic arrangements for dietary introduced and supervised by the superintendent, and to that officer's constant attention to the selection and cooking of wholesome food for the prisoners. The Bhagalpur Central and District jails had a very low death-rate, the reasons given therefore being the absence of malaria, the careful administration of prophylactic doses of cinchonidine, the great care and attention bestowed on the sick, and careful supervision in the preparation and cooking of food.

The year was a dry one in the North-Western Provinces and Oudh, and the free population suffered but little from malarial fevers. There was, however, widespread scarcity throughout the province, much more intense than in 1895, and the health of the classes from which the jail population is chiefly drawn was undermined and weakened. While the absence of rain lessened the malarial influences, it, on the other hand, led, owing to failure of the crops, to a contracted food-supply and enhanced rates, a condition of affairs which appears to have been more effective than malaria in producing deterioration in the health of the poorer classes. A large majority of the men admitted were consequently in

* Not re-printed.

bad health ; and owing to the increase of crime, the jails were more or less overcrowded. The comparatively low death-rate under these circumstances shows that every attention was paid to preserving the health of the prisoners.

In the Punjab, the favourable results of the year are ascribed to the general healthiness of the dry year, to the practice of giving a daily dose of cinchonidine to all prisoners in the autumn months, to the great pains devoted to the allotment of tasks, and the treatment and care of the prisoners by the medical officers in charge of them, and to the issue of extra clothing to the convalescents and sick in the winter months. In 20 of the Punjab jails there were no deaths from dysentery or diarrhœa ; and it may be mentioned in this connection that the issue of boiled water for drinking is now limited to the Amritsar, Lahore Female, and Dharmsala Jails.

No explanation is given of the excessive mortality in district jails in the Bombay Presidency as compared with that in central prisons. It appears that the longer the residence in district jails the higher the mortality, and that therefore prisoners confined in those district jails are unnecessarily exposed to preventable risks. This high mortality in district jails, and the prevalence of pneumonia in the jails at Ahmedabad, Hyderabad, Shikarpur, and in the Sind Gang, are deserving of attention. In consequence of its unhealthiness, proposals have been submitted for closing the Shikarpur Jail, and transferring the prisoners to Sukkur.

The prisoners admitted into the Yeotmahl Jail in Berar were nearly all in indifferent or bad health, but there was a good deal of overcrowding throughout the year ; and it appears from the Sanitary Sheet that the condition of the barracks is not satisfactory.

The scarcity that prevailed in 1895 in the Central Provinces, and led to a greatly increased mortality among the prisoners—nearly double of that in 1894—developed in 1896 into actual famine extending over the greater part of the province. The condition of the prisoners on admission was consequently worse than that described in the report for 1895, and the results are seen in the great increase in the sickness and, especially, in the mortality. The primary cause of the dysentery which was so marked a feature of the sickness and mortality of the year, was undoubtedly a low and anæmic condition, the result of chronic starvation. A so-called scorbutic form of dysentery is under such circumstances developed, and the patient, as a rule, rapidly succumbs. But the comparatively low mortality in some of the jails furnishes some ground for the suspicion that in some of the others there may have been local circumstances, which, if they did not aggravate the condition just described, at least failed to ameliorate it.

The year is stated to have been a healthy one in Madras Presidency, and the sickness generally was less than in 1895. Quinine was issued as a prophylactic in some of the jails, but not with the necessary regularity ; and the results were therefore disappointing. Measures have been taken to remedy the local defects to which the high mortality of the Rajamundry Jail was partly ascribed. The low mortality in the Trichinopoly Central Prison, which received weakly men from some other jails, could only have been attained through careful supervision and attention to every detail connected with the feeding of the prisoners, and the sanitary conditions under which they are placed.

Progress in reduction of death-rate. — The following table shows that the lustre 1892–96 was more healthy than its predecessor, and that mortality from all the causes shown, except phthisis, was reduced for the jails of India as a whole :—

Year.	Strength.	Ratio per 1,000.									
		Admissions into Hospital.	Constantly Sick.	Deaths from							
				Cholera.	Remittent Fever.	Dysentery.	Diarrhœa.	Respiratory Diseases.	Phthisis Pulmonalis.	Anæmia and Debility.	All causes.
1887–91 ...	459,442	1,134	38	3·53	1·68	6·80	3·29	6·15	2·45	1·98	34·11
1892–96 ...	523,288	1,058	41	1·97	1·25	6·59	2·12	5·59	2·71	1·81	29·77
1896 ...	110,090	983	41	1·27	1·07	5·91	1·98	5·28	3·07	1·43	27·69

As the central prisons are those in which sanitary carefulness has the best chance of proving its beneficialness, a similar table is next added dealing with them :—

Year.	Strength.	Ratio per 1,000.									
		Admissions into Hospital.	Constantly Sick.	Deaths from							
				Cholera.	Remittent Fever.	Dysentery.	Diarrhœa.	Respiratory Diseases.	Phthisis Pulmonalis.	Anæmia and Debility.	All causes.
1887–91 ...	192,841	985	36	4·71	1·13	5·75	3·34	5·58	2·63	1·89	32·79
1892–96 ...	234,520	940	40	1·74	·58	4·72	1·14	4·41	3·59	1·21	24·56
1896 ...	49,680	849	38	·26	·42	4·41	·95	4·21	4·11	·81	21·50

Here also the health of the second quinquennium was better than that of the first, and the ratio of mortality from each cause shown, again with the exception of phthisis, reduced. If now for the first lustrum the ratios of the central jails be compared with those of the jails of India as a whole, it will be found that the general ratios were lower in the central jails, as well as the death-rates from remittent fever, dysentery, respiratory diseases, and debility ; whereas the death-rates from cholera, diarrhœa, and phthisis were higher in the central jails. In the second five-year period all the ratios were lower in the central prisons, except the death-rate from phthisis. The general conclusion is that, except with regard to tuberculosis, the central prisons are more healthy than the jails as a whole, and more healthy than in the past ; and that this exception seems to indicate a want of sufficient fresh air for each prisoner.

Mortality of prisoners and of troops compared.—A table is, as usual, here given to compare the mortality of prisoners in 1896 with that of soldiers. Taking the death-rate of European troops as unit, the death-rate of native troops will be represented by 0·7, and the death-rate of prisoners by 1·9. The mortality of prisoners was comparatively high as regards cholera, bowel complaints, spleen diseases, anæmia and debility, respiratory diseases, and tubercle of the lungs. Only from fevers was the European soldiers' mortality highest. The enormously greater liability of the prisoners to death from bowel complaints is well shown in the table. Taking the mortality of the native troops from fevers as 1, that of the prisoners is 1·4, and that of the European troops 4·2. Taking the mortality of the native troops from bowel complaints as 1, that of the European troops is 1·2, and that of the prisoners 14·1. Taking the mortality of the European troops from respiratory diseases as 1, that of the native troops is 4·8, and that of the prisoners 6·9. While the liability of the native soldiers to die from respiratory diseases was less than that of the prisoners, yet these diseases made up a larger percentage of the total deaths among native soldiers than among prisoners. The chief cause of death among European troops was fevers, among native troops respiratory diseases, and among prisoners bowel complaints. Of course, for obvious reasons, too much must not be made of the comparison here instituted :—

Causes of Death.	Died per 1,000 of Average Strength.			Relative Liability in Percentages.				Percentage in Deaths from all causes.		
	European Troops	Native Troops.	Prisoners.	European Troops.	Native Troops.	Prisoners.	Total 100.	European Troops.	Native Troops.	Prisoners.
Cholera	·89	·69	1·27	31	24	45	100	6·0	6·7	4·6
Fevers*	6·81	1·61	2·19	64	15	21	100	45·9	15·8	7·9

* Enteric, intermittent, remittent, and simple continued fevers. † Includes acute and chronic pneumonic phthisis.

General Population.

General remarks.

It has frequently been indicated that the figures with which this chapter deals are approximately accurate in respect of only a few provinces. Matters are, however, improving, and a retrospect is encouraging, while there are signs of further improvement in the near future.

In Bengal ten years ago, births were registered in only 45 towns,* and the birth-rate obtained was only 21·04 per thousand of their population; in 1896, births were registered throughout the province, except in a few tracts, and the millesimal rate obtained was 38·03. In Assam and Lower Burma, the birth-rates have risen from 27·55 and 22·57 per 1,000 respectively in 1886 to 33·69 and 32·27 in 1896. In the Punjab there was less room for improvement, but the 39·47 per 1,000 registered in 1886 has risen to 43 in 1896, and the percentage of male to female births, though still the highest in the country, has fallen from upwards of 115 to 110·1.

A notable advance towards improvement in the collection of vital statistics has been made in the North-Western Provinces, where an important resolution dealing with sanitation has been issued by the Local Government. This resolution, which will be found on page 141, is primarily concerned with the reconstitution of the Sanitary Board of the province, but is certain to have far-reaching effects on the advance of sanitation generally, and the quality of registration will share in the improvement.

The registration of births is peculiarly defective in towns, and, in nearly every province, the average of the urban is lower than the average of the rural birth-rates. The birth-rates in rural areas, no doubt, gain at the expense of the urban rates on account of the custom of women who have been born in the country leaving their residences in the towns and going to their parent's homes in the country when about to become mothers. But neglect to register is the principal cause of low urban rates, and it is astonishing that Local Governments should appear to acquiesce in the practical disregard of the laws which they have prescribed.

There are obvious reasons why the death-rates should be less likely to suffer from neglect than the birth-rates, and the death-rates are generally higher in the towns than in the rural circles. It is important, especially in towns, that we should know, not only how many persons have died, but that our knowledge of the diseases which have caused the deaths should be much more precise than it is. The practical utility of such information increases with the size and importance of the town, and in seaports such information in the interests of the public health and prosperity is almost indispensable. The necessary knowledge cannot be obtained without the employment of a sufficient professional agency, and this will cost money. It may be hoped that the time is not far distant when such agencies will be established.

For the present returns are useful mainly for purposes of comparison, and are based on the population totals obtained at the last census. In their reports some of the provincial Sanitary Commissioners give calculations showing the rates based on the estimated actual population. In a few provinces such calculations are useful and interesting; in others they serve only to magnify existing errors of omission.

The following table shows the monthly incidence of mortality from all causes in each province :—

Statement showing the Deaths from all causes, according to Months, in the different Provinces of India during the year 1896.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION. 1896.	1895.

* The more extended registration of earlier years was limited on account of its extreme imperfection

In India as a whole in 1896 the number of deaths recorded was greater in each of the first nine months and less in October, November, and December than in 1895. A comparison with the average number of deaths recorded throughout the country, month by month, in the last five years shows that while the numbers of deaths in the first nine months of 1896 were in every instance much above the average, the numbers registered in the last three months were greatly below it.

In Bengal the year 1896 was particularly unhealthy, both on account of abnormal meteorological conditions and the consequent scarcity in many parts of the province, which led to high prices of food-grains everywhere. In Bengal towns registration is compulsory, the work being performed by the town police. Since 1892, the statistics regarding rural areas have been collected by the village watchmen and registered by them at police stations and out-posts. From all districts it is reported that magistrates and sub-divisional and police officers have been careful to look into registration while on tours of inspection. The inspectors of vaccination were employed in checking entries in registers; they examined entries relating to 204,424 births and 152,245 deaths, detecting omissions in 1·35 per cent of the former, and 1·12 per cent of the latter. Omissions were brought to the notice of the magistrate and police-officer, and the defaulters punished when the occasion required it. The number of persons fined for neglect was 1,969, and the amount realised as fines Rs. 2,857-1-0, against 2,049 and Rs. 3,153-14-0 respectively in 1895; while 408 persons were let off with a warning, against 427 in the previous year. **Bengal.**

The number of births recorded was 2,703,486, against 2,458,623 in 1895, and the birth-rate was 38·03, against 34·59 in the previous year. This rate, although still far behind the estimated provincial birth-rate of 50 per 1,000, exhibits a very satisfactory improvement in registration. Among the districts, the highest rates were recorded in Noakhali 48·98, Faridpur 47·02, and Tippera 45·66; the lowest in the 24-Parganas 25·82, Hooghly 26·87, and Burdwan 31·11. In rural areas, where the rates varied between 78·17 per 1,000 in Phulbaria, in Mymensingh, and 15·37 in Burdwan rural circle, the average was 38·64, against 26·18 in the towns. In 22 rural areas the rates were over 50, and in 63 others over 45 per 1,000. In eleven towns, as compared with only four in 1895, the rates were above 40 per 1,000. The highest rates were 50·80 recorded in Jamalpur, 47·45 in Bajitpur, and 44·43 in Madaripur; the lowest were 10·37 in Maniktola, 10·15 in Nalchiti, and 7·61 in Jhalakati, in Backergunge; although the rates in Maniktola and Jhalakati are higher than in 1895 the rate in Nalchiti is much lower, and in all these towns the rates are lower than the quinquennial averages. The proportion of male to female births was 106 to 100, the percentage of male births varying in the districts between 114 in the 24-Parganas and 103 in Noakhali; in the towns, between 157 in Jhalakati and 78 in Barisal; and in rural areas, between 133 in Asanpur (Murshidabad) and 89 in Manihari (Purnea). The largest number of births was recorded in the month of March, and the smallest number in July.

The number of deaths registered was 2,428,830, as compared with 2,231,458 in 1895, and the death-rate was 34·17 per 1,000, against 31·39 in the previous year and 30·67 the mean of the previous five years. The highest district death-rates were registered in Darjeeling 51·43, Muzaffarpur 46·70, and Backergunge 43·82; while the lowest were recorded in Singhbhum 25·55, Puri 24·88, and the Sonthal Parganas 23·76. The highest rate obtained in any rural area was 68·36 in Falakata in Jalpaiguri, and the lowest 13·40 in Netrokona in Mymensingh, the average, 34·07, being slightly lower than the average of town circles, 36·14. The towns in which the highest death-rates were recorded were Bhadreswar 58·30, Bettiah 57·46, and Kotrung in Hooghly 56·15; those in which the lowest rates were registered were Arrah 16·20, Raghunathpur 15·92, and Maniktola 15·70. One of the lowest birth-rates was registered in Maniktola, and it is partly explained by the disparity of females among the population, but the low death-rate must be explained by defective registration. Among Hindus and Muhammadans the death-rates were nearly alike, 34·54 and 34·26 per 1,000 respectively; among Buddhists and "other classes" the rates were also similar, 27·64 and 27·58, while among a population of upwards of 190,000 Christians the rate was 19·99 per 1,000.

In every month except October, November, and December the death-rates were higher than the quinquennial means, the excess being greatest in March and June. This excess is mainly due to the large number of deaths which were recorded as due to fever in these months, while cholera was particularly prevalent from March to June inclusive. On the other hand, the death-rates were lower than the average in the last quarter of the year, due to a falling off in the mortality ascribed to fever.

Infants under one year of age died at the rates of 247·76 and 198·27 per 1,000 males and females, calculated on the numbers living at the census of 1891. Boys and girls over one and under five years of age died at the rates, respectively, of 49·40 and 41·86 per 1,000. At all age periods the male death-rates were the higher, the average death-rates of males having been 36·98 per 1,000, and of females 31·38.

The number of European seamen who arrived in the Port of Calcutta was 17,053, against 18,015 in 1895, and the average daily population in 1896 was 1,124, against 1,431. The total number of deaths was 39, against 40 in the previous year, but, on account of the smaller population, the death-rate was higher, 34·69, as compared with 19·56. The average number of the native floating population is calculated to have been 25,630, and 219 deaths among them gave a death-rate of 8·54 per 1,000, against 4·79 in 1895.

Assam.

The area in which the statistics of births and deaths were collected in Assam remains the same as in previous years, namely, the Surma and Brahmaputra valleys and a few selected areas in the Hill districts; the latter, except in the case of the Khasi and Jaintia Hills, being excluded from the general statistics. In the districts of the Surma valley and in Goalpara the work of registration is carried out by paid *chaukidars;* but in Assam proper the work is performed without payment by village headmen, who are known as *gamburas*. The registers are inspected by the police and vaccination establishments, and the monthly returns of vital statistics are scrutinized in the office of the Sanitary Commissioner, who, when he detects obvious inaccuracies, brings the matter to the notice of the district officer with a view to enquiry being made. The Sanitary Commissioner was not satisfied with the inspection work carried on by the inspectors of vaccination, and in a special circular drew the attention of civil surgeons to the matter, which, however, does not seem to have received at their hands the attention its importance deserves. The quality of the work of inspection done by the police although showing signs of improvement still leaves much to be desired. Registration of vital occurrences is compulsory in twenty of the towns, but the provisions of the law seem to be generally neglected for the birth ratios in these towns are, except in four cases, below the provincial average. There were 140 persons prosecuted for neglecting to register, and 103 convictions obtained, against 192 and 142 respectively in the previous year, and the average penalty imposed was 11 annas and 3 pies.

In the selected villages in the Garo Hills the birth-rate was 37·15 per 1,000, and the death-rate 33·58, against 36·75 and 29·79 respectively registered in 1895. In Kohima, a similar improvement in registration is apparent, the birth and death rates having been 28·64 and 25·27 per 1,000, against 20·21 and 19·09 in 1895. As might be expected from the conditions under which the statistics are collected, the birth-rates are higher in the Surma valley than in the rest of the province, except Goalpara, but for some reason the difference does not seem to extend to the death-rates. The total number of births registered in the province, excluding the selected areas above mentioned, was 169,172, against 155,631 in 1895, and the birth-rate, which is the highest yet recorded, was 33·69 per 1,000, against 31·0 in that year and 30·39 the mean of the previous five years. The highest district birth-rate was 42·71 registered in Goalpara, and this was followed by 38·02 and 33·18 registered, respectively, in Sylhet and Cachar, the two districts of the Surma valley. The lowest rates were 26·36 registered in Kamrup, 25·40 in the Khasi and Jaintia Hills, and 24·57 in Nowgong. In the last named district, where the lowest rate has been registered for years past, the public health has been very bad, but the low rate must be largely due to defective registration. In the rural areas the recorded birth-rates ranged from 51·95 in Silchar to 17·72 in Mangaldai and 16·19 in the tea garden circle in Kamrup; the average was 33·83, against 27·59 in the towns. Among the latter, the highest rates were 43·95 per 1,000 registered in Dibrugarh, 40·19 in North Lakhimpur, and 37·44 in Barpeta; while the lowest rates were 17·55 in Silchar, 13·47 in Dhubri, and 11·44 in Mangaldai. The statement that the low birth-rates in towns is in a measure due to the great excess of the male population is well exemplified in Silchar and Dhubri; while the population of Mangaldai is so small that great fluctuations in the birth-rate must occur. In the province as a whole there were born 107·44 males for every hundred female infants born. The percentages in the districts varied from 111·13 in Sibsagar to 105·25 in Goalpara; in the towns the variation was very great, ranging from 146·15 in Jorhat to 58·33 in Hailakandi; while in the rural areas the variation though not so extensive was very great, from 130·53 in Dum Duma to 63·63 in the tea-garden circle in Goalpara.

The total number of deaths registered was 182,417, against 169,304 in 1895, and the death-rate, which is the highest ever registered in Assam, was 36·33 per 1,000, as compared

with 33·72 in the previous year and a quinquennial mean of 30·17. Among the districts the highest death-rates were registered in Nowgong 45·70, Goalpara 42·11, and Darrang 40·52, while the lowest were 30·72 in Cachar, 30·06 in the Khasi and Jaintia Hills, and 29·39 in Sibsagar. In Nowgong and Darrang the death-rates were, respectively, 21·13 and 13·16 per 1,000 higher than the birth-rates. In rural areas the death-rates recorded ranged from 72·07 in the tea garden circle in Goalpara to 15·23 in Lakhimpur, and the average was 36·30, slightly lower than the average death-rate in towns, which was 37·92. Among the towns the highest death-rates were recorded in Tezpur 68·06, in Dhubri 60·31, and in the small town of Mangaldai 55·79 ; while in Sylhet 26·10, Jowai 22·29, and Shillong 18·31, the lowest rates were registered. Among the various sects, by far the largest death-rate, 59·49 per 1,000, was registered among "other classes," a community numbering nearly half a million. Judging by the extreme variation in the death-rates, 225·35 to 33·84, in the adjoining districts of Darrang and Kamrup, it would appear that persons who are not identified are included among "other classes." The death-rate of Muhammadans was 36·32, of Christians 35·07, and of Hindus, who constitute about three-fifths of the population, 32·86. The largest number of deaths were recorded in the months of November and December, and the smallest numbers in April, September, and August.

Excluding the population of the Khasi and Jaintia Hills, the death-rates of infants calculated on each thousand living at the census of 1891 were among males 216·29 and among females 195·51 ; among boys and girls between one year and five years the rates were 43·38 and 42·38 per 1,000 respectively. At the age periods between 15 and 30 only were the female rates the higher ; the average death-rate having been 37·45 for males and 35·12 for females.

North-Western Provinces and Oudh.

In detailing briefly the main features of the registration of vital statistics in the North-Western Provinces and Oudh in 1896, special account must be taken of the meteorology of that and the preceding year, for in 1895, and, especially, in 1896, these conditions were abnormal.

The early cessation of the monsoon rainfall in 1895, and the failure of the winter rains, caused a contraction of about 19 per cent. of the *rabi* area ordinarily under cultivation in that tract of country in the south of the province known as Bundelkhand. Here distress, due to bad harvests of the previous three years, had been extensively prevalent, and, in consequence of this addition to their misfortunes, the people began to suffer acutely. Relief works, which soon developed on an extensive scale, were opened, and by the end of May the people occupied on these works or receiving gratuitous relief numbered nearly 264,000. Distress was not limited to Bundelkhand, for in the neighbouring district of Allahabad, in Hardoi, Pilibhit, Garhwal and Almora, relief works on a moderate scale became necessary. With the onset of the rains of 1896, however, distress in these districts ceased, and the pressure of scarcity rapidly diminished in Bundelkhand. There was a severe outbreak of cholera among the relief-workers in Banda ; and in the distressed districts the death-rates were above the average, but only 26 deaths from starvation were reported. The monsoon rain of 1896 was deficient in Bundelkhand in June, and in July the rainfall generally was in defect to a serious extent ; while in September and October the rains failed altogether. In consequence of deficient rainfall the temperature, save in June, was abnormally high—the greatest excess being noted in September and October. Except in the north of Oudh, in the Meerut Division, and in the portions of the Agra Division, protected by irrigation against drought, the crops withered, and measures to afford assistance to the people had to be undertaken. In Bundelkhand relief works were reopened ; in other districts test works were begun, which in many instances developed into regular relief works.

The total number of births recorded was 1,660,387, as compared with 1,637,235 in 1895, and the birth-rate, 35·40 per 1,000, although lower than the mean of the previous quinquennium, 36·99, was higher than the rate recorded in 1895, which was 34·90. Among the districts the highest birth-rates were reported in Etah 52·76, Bulandshahr 51·14, and Agra 49·57 ; while the lowest rates were recorded in Azamgarh 24·0, Dehra Dun 23·05, and Naini Tal 22·11. Low birth-rates were recorded in eastern districts besides Azamgarh, and are attributed, in most instances, rather to the effect of recent agricultural distress and congestion of the population than to defective registration. The birth-rates registered in rural areas ranged from 71·65 per 1,000 in Rasulpur in Muttra to 10·91 in Kotdawara in Garhwal, the average being 34·91, as compared with 39·30 in town circles. Omitting hill stations and certain other places where exceptional conditions exist, the extremes were rates of 61·41 in

Fatehpur-Sekri and 26·44 in Lalitpur. In Bareilly there was a marked improvement in registration, and the rate rose from 30·49 in 1895, and an average of 28·87 in the previous quinquennium, to 39·54. In this town, however, an assistant surgeon was specially deputed to the work of improving registration. The success achieved by him may, perhaps, prove an incentive to the authorities of some other municipalities where improvement in registration is greatly needed. The percentage of male to female births was 108·86, varying in the districts between 113·15 in Dehra Dun and 102·2 in Garhwal.

Registration was tested by revenue, civil and police officers, and members of district boards. The number of birth entries in the registers examined was 144,049, and 2·73 per cent. of omissions were detected; death entries in 130,219 cases were examined, and the percentage of omissions discovered among them was 2·37. The vaccination staff examined the entries relating to 233,027 births and 192,173 deaths, and discovered 1·34 and ·73 per cent. of omissions respectively. Regarding the checking of registers by the vaccination staff the Sanitary Commissioner makes the following observations, quoted because they are of interest in respect of objections which have been made to the use of this agency as an auxiliary in the work of registration :—

* * * * "The chaukidar who keeps the birth and death registers in a village is by far the most "useful assistant to the vaccinator. Without him and his aid it is extremely difficult for the last-"named official to obtain reliable intelligence as to what children have been born in a village and "where they live. The result is that a successful vaccinator would be the last person who would "voluntarily report an omission or mistake on the part of the chaukidar, as on the occurrence of his "next visit to this village, the chaukidar would either be absent or give little or no assistance. I have "never expected any material help, so far as returns go, from this particular checking agency, but it "does not follow that it is not useful in practice. Although no report is made of the incident, the "mistake is generally rectified on the spot by the chaukidar and the vaccinator together, and the "practical result is more accurate registration."

It is remarkable, that, in spite of the distress that was prevalent in the province, the total number of deaths, 1,562,894, was considerably less than the number of births registered. The death-rate was 33·32 per 1,000, higher, it is true, than the rate of 1895, which was 29·13, but not much higher than the quinquennial mean 32·20, and very close to the mean of the death rates of 1893 and 1894, years in which the lowest (24·10) and highest (42·51) death-rates ever recorded in the province were registered. An analysis of the district death-rates shows that in 29, generally the northern and south-western, the rate was higher than the quinquennial average, and in 19, all eastern except Etawah, below it. Seeing that to fevers a death-rate of 25·71 is ascribed, it is interesting to note how far the fever-rates influence the departure from the normal of district rates. In 32 districts the fever death-rates were higher than the average of the preceding five years, and in all cases save four, Allahabad (where the total death-rate was slightly below the average), Farukhabad, Sitapur, and Partabgarh (where the rates were above the average), the divergence from the normal of the total death-rates appears to be due to fever. In Allahabad, where the total death-rate is slightly in excess of the normal in spite of a fever death-rate which is below it, the divergence is due to an excessive mortality from small-pox, which is 4·02 per 1,000 higher than the normal rate of ·08. In Farukhabad and Sitapur, where the total death-rates were slightly below, in spite of fever death-rates above the normal, the divergencies were due to the cholera-rates being lower than ordinary. The case of Partabgarh is peculiar; the quinquennial average death-rate from fever is only 8·56, while the death-rate under "other causes" is very high—by far the highest in 1896 in any district where the fever death-rate is low. Here, also, the low death-rate was due to the comparatively small number of deaths from cholera. In 13 districts there was more, and in 35 less, cholera than usual. In all districts, except Garhwal, Naini Tal, Kheri, Gorakhpur, Azamgarh, Ghazipur, and Ballia, the small-pox death-rates were above the average. In 38 districts the deaths attributed to dysentery and diarrhœa were less numerous than usual. The highest district death-rates were 67·40, 53·56, and 53·22 per 1,000 recorded, respectively, in Jhansi, Bareilly, and Pilibhit; while the lowest were 23·48, 22·98, and 22·32 registered in Ballia, Ghazipur, and Azamgarh. In rural circles the rates ranged from 125·31 and 99·55 in Madanpur and Birdha, both in the Jhansi district, to 16·40 in Murdah in Ghazipur; the average, which was 32·59, was considerably less than the average of town circles, 39·11. In the towns, however, the death-rates were raised by the deaths of the famine-stricken who had sought refuge only to die in the poor-houses. This was the case in Lalitpur (death-rate 114·12), Hardoi (87·97), Mau Ranipur (70·65), Orai (57·23), and Jhansi (53·68); and in all these towns cholera contributed largely to the death-rates. High death-rates were recorded in Fyzabad-Ajudhya (49·51) and Cawnpore (47·43). The lowest urban death-rates recorded were 25·73 in Baragaon, 20·26 in Purwa, and 16·07 in Mubarakpur. The ratio of deaths among Muhammadans was 33·51 per 1,000, and

among Hindus 33·31 ; among "other classes" the rate was 35·17, while among the small population of Christians the rate was only 11·96.

The seasonal distribution of the mortality was abnormal. The death-rates followed the normal course, but on a higher level until May, when there was the normal fall till July, and the usual rise in August. The rise in September culminating in October began, but did not continue ; the usual fall in November took place to a lower level than usual, but, instead of the fall continuing in December, the death-rate rose. In short, the curve of the year was normal but on a higher level till May, normal in June, July, and August ; the autumn rise failed, and there was a rise, instead of a fall, in December. The Sanitary Commissioner explains the abnormalities by high temperatures, scarcity, small-pox and cholera in the early part of the year ; deficient rainfall and absence of the autumnal fever death-rate ;—the rise in December being due to the effect of scarcity. This explanation is supported by an examination of the mortuary statements. As might be expected, the death-rates of infants were high—241·16 per 1,000 for males and 228·20 for females ; boys and girls, between one and five years, died at the rates, respectively, of 57·73 and 54·98 per 1,000 ; at every age period, except 15–30, the male death-rates were the higher ; and the average death-rates were 34·68 for males and 31·86 for females, the discrepancy being due, in Dr. Thomson's opinion, to neglect in registering female deaths.

Punjab.

Details regarding the measures taken to improve the registration of vital statistics in the Punjab have been given in the reports of recent years. Improvement under present conditions can be secured only by inducing those responsible for the actual registration of births and deaths to take an interest in the work and carry it out thoroughly, and the frequent inspection of registers by tehsildars, vaccinators, and divisional inspectors of registration seems to be a promising method of stimulating this interest, provided that the inspections are thorough and that the practice in recording omissions is uniform. It seems, however, that tehsildars discover, on an average, only one omission in the registers of every five villages, the vaccinators find one omission in every two villages, while the divisional inspectors find three omissions in every village. The number of omissions detected by vaccinators in village registers varies remarkably in different districts, and the Lieutenant-Governor is doubtful whether an omission reported always refers to a single birth or a single death, or only to an error in the register. Arrangements have been made, however, to avoid mistakes of this kind. In the municipal towns, 34 persons were fined for omitting to register births, and 36 for omitting to register deaths, the average amounts of the fines varied from over Rs. 3 in some places to only one anna in others, and the attention of district magistrates has been drawn to this irregularity.

The total number of births registered in 1896 was 884,692, against 901,584 in the previous year, and the birth-rate was 43·04, slightly lower than in 1895 when it was 43·86, but considerably higher than the quinquennial mean of 39 per 1,000. Among the districts the highest rates were recorded in Gujranwala, Ferozepore, and Jhansi, 51·9, 50·8, and 49·8 per 1,000 respectively ; while the lowest were recorded in Kangra 31·0, Peshawar 30·0, and Simla 17·4. Extraordinary high birth-rates were registered in the rural areas of Dichkot, Pakhimian and Burki, due probably to errors in the numbers of the populations on which the rates were calculated, while in Kotkhai (16·8) in the Simla district, Balakot (11·6) in Hazara, and Domel (7·8) in Bannu, the rates were very low. The average recorded birth-rate in rural areas was 43·3, as compared with 40·8 in the towns. Among the latter, the highest rates were 58·1 returned from Chunian, a small town in the Lahore district, 56·4 from Sialkot, and 55·8 from Jalalpur ; the lowest rates were recorded in Buriya 20·6, Thanesar 19·1, both in the Umballa district, and Simla 16·7. The percentage of male to female births was 110·1, but there were great variations ; in the districts the percentages ranged from 136·9 in Peshawar to 106 in Kangra ; in the towns from 175·6 in Kila Didar Singh to 75·6 in Pakpattan ; and in rural areas from 200·4 in Rustam in the Peshawar district to 87·3 in Nizampur in Kohat. The smallest numbers of births were registered in April and May, and the largest numbers in October, November, and December.

The total number of deaths registered in 1896 was 648,099, against 601,972 in 1895. Owing to the deficient rainfall there was scarcity throughout the province in the latter part of the year. Timely preparations were made to prevent actual famine, and only three deaths from starvation were reported—all in the Ferozepore district. If the scarcity was severely felt, it is not apparent in the death-rate, which was only 31·53, as compared with 34,51 the average of the preceding five years. The death-rate was, however, materially higher than in 1895, also an exceptionally dry year. An examination of the mortuary returns shows that the death-rate of 1896 would have been almost as low as

that of the preceding year, 29·29, had it not been for the exceptional mortality in January and February, especially in the former month, when the death-rate was 1·67 per 1,000 in excess of the monthly average rate, which was rather less than 2·63 per 1,000 per annum. The large excess number of deaths which occurred in January are registered under the heading "fever," and were probably due to influenza, which appears to have been prevalent in the Punjab in the end of 1895 and beginning of 1896.

The highest district death-rates were recorded in Umballa 40·89, Karnal 40·37, and Kangra 40·28 per 1,000, and the lowest 24·10 in Muzaffargarh, 23·37 in Dera Ghazi Khan, and 22·85 in Gujrat. The death-rates were above the average in 12 districts, and below it in 19. The death-rates in rural areas ranged from 192 per 1,000 in Dichkot* to 5·4 in Domel, and averaged 31·2 per 1,000, as compared with 34·4 in towns. Among the latter the highest death-rates were recorded in Kaithal 48·96, Chunian 47·10, and Bhiwani 45·54, and the lowest in Shahabad (in Umballa) 25·28, Dera Ghazi Khan 25·11, and Sadhaura 23·65. Among Hindus the death-rate was 32·82 per 1,000, and among Muhammadans 30·51, the extremes being recorded among native Christians 17·31, and "other classes" 96·42. The low rate among native Christians is due to defective registration, and the high rate among "other classes" is explained by the fact that, while they number only 6,067, the deaths of persons whose religion and caste are unknown are registered under this heading. The death-rates of infants were 229·14 per 1,000 living among males, and 223·32 among females. Boys and girls, between one year and five years of age, died at the rates of 47·99 and 53·23 per 1,000 respectively. In the age-periods, from 5 to 40, the female death-rates were the higher, but over the age of 40 males had the higher rates. By far the largest number of deaths were registered in January. In February the number of deaths was considerably higher than the monthly average, and in May it was about the average, in all other months it was below; the lowest rates were recorded in April and July.

Central Provinces.

The year in the Central Provinces was one of exceptional drought; with the exception of a few showers in some of the districts in April and May, there was no rain from January to the onset of the monsoon. Although the rainfall of the monsoon was too heavy in some districts, it was on the whole favourable until the end of September, when it died away, and the fairly good rain, which fell in the third week of November, came too late to affect the prospects of the crops in the province. During the year seed was difficult to obtain on account of previous bad seasons, lands were hard to plough and germination was defective or failed altogether on account of drought, the autumn crops withered, and in large areas the want of moisture prevented the sowing of winter crops. The distress, which had been growing in various parts of the province for years, became during 1896 actual famine among the poorer classes of the population, particularly in the northern and central districts, and in Balaghat, Bhandara, and Raipur.

The deterioration of the public health, consequent on scarcity, is very apparent in the vital statistics; the birth-rate is the lowest of any in India, except Madras, where registration is extremely bad, while the death-rate is by far the highest. In the five years ending with 1894 the birth-rate in the Central Provinces was fairly constant; but in 1895 the birth-rate fell to 33·41 per 1,000, the lowest in 14 years, and in 1896 it has fallen to 31·72, or 6·67 per 1,000 lower than the quinquennial mean. The total number of births recorded was 301,427, against 317,432 in 1895 and 368,884 in 1894. Comparing the numbers of births recorded in the districts in the three years, it appears that, in the figures of 1895, there was a decrease in 16 districts, and an increase in four, namely, Nimar, Burhanpur, Betul, and Chhindwara, while in 1896, as compared with 1895, there was a decrease in 14, and an increase in six districts, namely, Nimar, Burhanpur, Saugor, Jubbulpore, Chanda, and Raipur. The provincial Sanitary Commissioner considers the increase apparent rather than real and due to improved registration, consequent on a keener interest in the condition of the people leading to greater zeal on the part of the local registering agencies.

There has been no change in the machinery for the collection of vital statistics in the province, and there was a slight falling off in the number of villages in which registers were checked by native superintendents of vaccination, from 2,801 in 1895 to 2,686. The figures obtained show, if reliance can be placed on the efficiency of the inspections, that the *kotwar's* work of registration is well done, for among 37,000 births there were less than 1 per cent. of omissions, and among 50,000 deaths less than 2 per cent. Among the districts the highest birth-rates were 44·0, 42·29, and 37·58 recorded, respectively, in Nimar, Burhanpur, and Raipur; while the lowest were 32·53, 21·88, and 21·75 recorded

* Where the population has been understated.

in Seoni, Saugor, and Damoh. In rural areas the recorded rates ranged from 51·09 in Sohela in Sambalpur to 13·33 in Khimlasa in Saugor, and the average was 31·79, or ·76 higher than in the towns. Among the latter the highest rates were recorded in Katol (59·43), a small town in the Nagpur district, Allipur (49·06) and Arvi (46·54), both small towns in Wardha; and the lowest rates were recorded in Sambalpur (16·40), and Rajim (15·20), a small town in Raipur. The percentage of males born to females in the province generally was 106·68, but in the districts the percentages varied between 113·73 in Saugor and 100·37 in Sambalpur; in town circles they ranged from 139·16 in Jubbulpore Cantonment to 73·17 in Burha in Balaghat; and in rural circles from 126·65 in Itarsi to 92·07 in Behir in Balaghat.

The total number of deaths registered was 468,469, as compared with 349,137 in 1895, and the death-rate was 49·31, as compared with 36·75 in the preceding year, and an average of 33·76 in the preceding five years. This mortality has never been approached, except in 1878, when a death-rate of 46 per 1,000 was registered. In every district in the province, except Burhanpur and Sambalpur, the death-rate exceeded the birth-rate, and in some districts the excess was enormous, *e.g.*, Damoh, where it was 66·53 per 1,000, Saugor 50·75, Mandla 45·96, and Murwara 40·49. The highest death-rates were recorded in Damoh 88·28, Mandla 73·68, and Saugor 72·63; while the lowest were recorded in Bhandara 36·64, Chanda 36·61, and Sambalpur 30·39. In rural circles the highest rate was 102·73 in Narainganj, and the lowest 21·41 in Sironcha; the average being 49·35, slightly higher than the urban average death-rate which was 48·79, but the latter rate was swollen at the expense of the former by the influx into towns of moribund immigrants from the rural areas. This was particularly the case at Damoh and Murwara, where the highest death-rates, 172·21 and 156·88, were recorded. The lowest urban rates were 22·16, 20·81, and 18·95 registered, respectively, in Hinganghat, Dhamtari, and Rajim. The death-rate among Hindus was 42·69, among Muhammadans 43·12, and among "other classes" 87·34. No explanation of the extraordinarily high death-rate among the "other classes" is given, but it may perhaps be assumed that, as in the Punjab, the deaths of the unknown are included. The greatest numbers of deaths were registered in August, September, and October, and the least in January, February, and March. The average monthly death-rate was 4·1 per 1,000 per annum, and the extreme fluctuations were recorded in January 3·27 and August 5·27. Among infants the death-rates per 1,000 living were for males 381·43, and for females 332·50; while boys and girls, between the ages of one year and five, died at the rates of 60·70 and 50·23. It is worthy of note that, as in 1895, in every age period the male death-rates were higher than the female death-rates, the average among the former being 53·55 per 1,000, against 44·95 among the latter.

Berar.

The total number of births registered in Berar was 109,013, as compared with 105,952 in 1895, and the birth-rate was 38·3 per 1,000, against 37·2 in the previous year, and a quinquenninal mean of 38·6. In three of the districts, Buldana 44·1, Akola 41·1, and Ellichpur 40·0, rates above the average were recorded, and in the remaining three, namely, Amraoti 37·9, Basim 34·5, and Wun 31·8, the rates were below the average. In rural areas the highest recorded rate was 58·3 in Kingaon Raja in Buldana, and the lowest 26·1 in Bittergaon in Basim, the average, 38·3, being slightly higher than the average in town circles, which was 38·0. In the municipal towns the average birth-rate was 37·4 per 1,000, and ranged from 47·8 in Buldana to 28·9 in Yeotmal. In the province as a whole 105·3 male infants were born for every 100 female infants; the extreme variations of the percentage were 128·7 in the town circle of Patur in Akola, and 77·4 in the town circle of Morsi in Amraoti. In the municipal towns the highest percentage was 111·4 in Amraoti City, and the lowest 93·7 in Buldana. It is worthy of note that in these towns registration is fairly efficient; in the latter, indeed, the highest birth-rate was recorded. The greatest number of births (11,784) was registered in August, and the least (6,625) in February.

The number of deaths recorded was 124,787, against 141,937 in the previous year, and the death-rate was 43·8, as compared with 49·9 in 1895, and an average of 38·8 in the five years ending with that year. In only two of the districts—Wun, where the rate was 50·5, and Amraoti, where it was 45·6—were the rates higher than the provincial average; the lowest district rates were 42·1 recorded in Akola and 38·8 in Buldana. The rates in rural areas varied from 62·0 in Panderkowra in Wun to 29·8 in Ansing in Basim, and averaged 43·8, against 44·0 in town circles. In municipal towns the average rate was 43·3 per 1,000, and ranged from 59·5 in Yeotmal to 31·8 in Ellichpur City. Of the various sects, the Muhammadans had the lowest death-rate, 39·1, the Hindus came next with 42·7; among native Christians, a very small community, 41 deaths gave a death-rate of 83·3,

and among "other classes" the high rate of 78·0 was recorded. It appears that persons of certain low castes, which are included in the census population among Hindus, are apt to be included in the mortuary returns among "other classes." The mortality of the first five months of the year was about double the average; in June and July the deaths fell to near the mean; and in August they fell below it, and so remained to the end of the year. This divergence from the normal is believed by the provincial Sanitary Commissioner to be due to the unusually high temperature which prevailed during the first half of the year and lowered the state of the public health, and the exceptionally light rainfall in the third quarter which reduced to a minimum those monsoon conditions which tend to raise the death-rate. Among infants under one year the mortality among males per 1,000 living at that age in 1891 was 273·0, and among females 233·0; while, among boys and girls between one year and five years of age, the rates were, respectively, 97·5 and 81·5. At all age periods, except those between 10 and 30, the female death-rates were the higher. The death-rates according to sexes were 45·5 for males and 42·1 for females.

Madras.

The system under which vital statistics are collected in the Madras Presidency was described in this report for 1893. Since then, no important change has been made in the agency, and after considering the question in 1896, the Government of Madras came to the conclusion that they could not afford to make any radical change in the *personnel*. Sanction was, however, accorded in September to certain changes, which will directly and indirectly further the cause of accurate registration. These were:—

"(1) Candidates for the public service and schoolboys, who were born in municipal towns in which "the compulsory system of registration has been in force for many years, should be required, after a "certain date, to produce attested extracts from birth registers.

"(2) That the number of union and municipal registrars be calculated with reference to the "population and area of the municipal towns and unions.

"(3) That printed forms (in lieu of existing loose forms) bound into books be supplied to all "registrars.

"(4) That steps be taken to punish negligence.

"(5) That special inducements be offered to all municipal servants for reporting cases of unregistered "births or deaths."

Dr. King also addressed a circular letter to all municipalities directing their attention to the importance, from the sanitary, economic, and medico-legal points of view, of insisting on prompt registration. It may be hoped that these measures will secure some improvement in registration, which continues to be backward in Madras. In 1896 the birth and death rates were lower than the rates recorded in any other province.

During the year, the births of 979,981 children were registered, equal to a birth-rate calculated on the census population of 29·9 per 1,000, as compared with 29·1 in 1895, and 27·2 the mean of the previous five years. There was an increase in 1896 in the birth-rates in 12, and a decrease in 9, of the 22 districts, as compared with 1895, while in one district, South Arcot, the rates for both years were equal. As compared, however, with the average of the previous five years, there has been an increase in all districts, except Coimbatore, Kurnool, and Trichinopoly. In Ganjam, Vizagapatam, and the Nilgiris a considerable improvement in tracts long notorious for bad registration is recorded. The highest district figures obtained were 39·5 in Chingleput, 34·3 in Bellary, and 33·9 in Kistna, while the lowest were 26·6 in Ganjam, 25·8 in Godaveri, and 22·5 in Malabar. It may be noted that the birth-rate in Ganjam is 8·4 per 1,000 above the average, that in Godaveri 3·4 above the average, while the rate in Malabar, although lower than in 1895, is 1 per 1,000 above the average. In rural areas the recorded rates ranged from 44·4 per 1,000 in Gajapatinagaram in Vizagapatam to 10·8 in the Agency tracts of the Ganjam district; and the average was 29·5, against 34·4 in the town circles. The highest rates recorded in towns were 56·9 in Vaniyambadi, which again heads the list, 50·5 in Tenkasi, and 45·9 in Periyakulam; the lowest rates were 11·3 recorded in Pithapuram, 9·9 in Samalkot, both towns in the Godaveri district, and 9·0 in Paramagudi in Madura.

The percentage of male to female births in the Presidency generally was 104·8. Curiously enough, the urban and rural percentages, 105 and 104·8, were approximately the same, although in town circles the percentage varied between 164·6 in Sendamangalam and 76·4 in Paramagudi, while in rural areas the highest was 236·3 in the Settinandal villages in Madura, and the lowest 85·1 in Cochin. The greatest numbers of births were recorded in July and August, and the least in February.

The number of deaths registered was 675,787 and the death-rate was 20·6, as compared with 19·6 in 1895, and a quinquennial mean of 20·7 per 1,000. Among the districts the highest rates were 27 and 24·7 per 1,000, recorded, respectively, in the Nilgiris and Tanjore, while the lowest were 17·1, 16·9, and 15·7 registered in Godaveri, Nellore, and Malabar, respectively. In rural areas the rates fluctuated between 33·3 in Coimbatore and 11·3 in

Kurumbaranat, the average having been 19·9 per 1,000, or about 9 per 1,000 less than the urban average, which was 29·0. The highest rates recorded in towns were 72·4 in Kilakarai, 53·8 in Vaniyambadi, and 43·0 in Coonoor, while the lowest were 10·1 in Virudupatti, 8·1 in Paramagudi, and 6·6 in Samalkot. In the Presidency town the birth-rate was 41·5 and the death-rate 38·2. The Hindus, who constitute about 90 per cent. of the population, had a death-rate of 21·0 per 1,000, the Muhammadan death-rate was 18·1, the native Christian community, numbering 766,987, had a death-rate of 15·1, while the comparatively small population of "other classes" died at the rate of 9·3. The lowest death-rate was recorded in April, and by far the highest in December, due chiefly to an enormous rise in the number of deaths from cholera in that month. The death-rate among male infants was 150·9 per 1,000, and among females 124·7, calculated on the census population of infants.

Coorg.

The number of births registered in Coorg during 1896 was 4,606, against 4,567 in the previous year, and the birth-rate was 26·62, against 26·39 in 1895, and a quinquennial mean of 21·95. The rates obtained in rural areas ranged from 33·82 in Nanjarajpatna to 20·38 in Yedenalknad, the average being 27·81, or more than 13 per 1,000 higher than the average in town circles, which was only 14·44. It is alleged that the defective birth-rate in Coorg is due to the excess of males among the population ; this is no doubt true in a measure, but the excess of males in the urban population is only a fraction per cent. higher than in the rural areas, and yet the birth-rate in the latter is nearly twice as high as it is in the former. In Mercara the birth-rate was only 7·96, as compared with 23·16 in Virajendrapet but in Mercara the proportion of females is higher than in Virajendrapet ; certainly fluctuations in the birth-rate in a small population (7,034) like that in Mercara must be expected, still, as the quinquennial average rate is only 11·57, it must be concluded that defective registration is also to blame for the small recorded birth-rates. The average percentage of male to female births was 97·68, ranging from 133·33 in Mercara to 62·50 in Somvarpet.

The total number of deaths was 4,574, against 5,073 in the previous year. The death-rate, which for the second time in the history of registration in Coorg was lower than the recorded birth-rate, was 26·43 per 1,000, against 29·31 in 1895, and 26·26 the quinquennial mean. In the rural areas the average death-rate was 25·84, varying between 29·49 in Mercara and 22·37 in Padinalknad. In town circles the average death-rate was 32·43, but this is increased at the expense of the rural rates, by the inclusion of the deaths of residents in the latter who died in the dispensaries in the towns ; for instance, in Mercara the death-rate registered was 22·75, but if the deaths of 45 coolies who died in hospital are omitted the birth-rate falls to 16·35 ; similarly, in Virajendrapet, where the highest death-rate (56·89) was registered, if the deaths of 141 coolies are deducted the rate falls to 25·18 per 1,000. Among Muhammadans the death-rate was 20·61, among Hindus 26·80, and among "other classes" 31·03. In February, April, and October the fewest deaths occurred, and in July the largest number. Among infants under one year of age, the death-rates per 1,000 living were 260·89 for males and 230·87 for females. Boys between the ages of one year and five died at the rate of 34·09 per 1.000, and girls at the rate of 30·28. In all age periods, except those between five and 30, the male death-rates were the higher.

Bombay.

In the Presidency of Bombay, including Sind, there were registered 691,847 births, against 674,304 in 1895, and the birth-rate rose from 35·83 per 1,000 in that year to 36·76, as compared with a quinquennial average of 35·41. The highest district birth-rates were obtained in the Collectorates of Ahmednagar 47·55, Khandesh 47·30, Nasik 46·94, and the lowest in Upper Sind Frontier 26·18, Thar and Parkar 25·47, and Hyderabad 18·35. In rural areas the highest rate recorded was 63·54 in Nandgaon in Nasik, and the lowest 11·02, in Tando Bago in Hyderabad, while the average was 37·76, as compared with an average of 29·61 in town circles. Among the latter, the highest rates were recorded in Vengurla in Ratnagiri (61·64), Borsad 56·26, and Sangamner in Ahmednagar 53·22, while the lowest were registered in the City of Bombay 19·35, Thana 17·18, and Nasik 17·78. In 16 municipalities rates higher than 40 per 1,000 were obtained. The percentage of male to female births was 107·92, varying in the districts between 136·23 in Upper Sind Frontier and 101·72 in Bijapur. The excess of male births registered in the districts in Sind is attributed by the local authorities to (*a*) the greater consequence attached to the birth of a male, and (*b*) to the desire to prevent female children being vaccinated. As usual, the least number of births were recorded in February, and the largest number in July.

The total number of deaths registered was 596,472, as compared with 538,540 in 1895, and the death-rate was 31·69 per 1,000, against 28·61 in the previous year, and 29·57 the mean of the previous five years. The highest district rates were recorded in the Collectorates of Nasik 43·76, Broach 39·98, and Khandesh 39·0, while in Shikarpur 21·91, Thar and Parkar 21·51, and Hyderabad 17·46, the lowest rates were registered. In rural areas death-rates ranged from 50·35 in Nandgaon to 10·41 in the rural circle of Karachi, the average being 30·92, against 37·21 in the towns. The highest urban death-rates were recorded in Ahmednagar 60·00 per 1,000, Nasik 54·90, and Godhra 51·19. In Ahmednagar, where the quinquennial mean death-rate, 53·47 per 1,000, is very high, the death-rate given under "other causes" is 32·42 per 1,000; six deaths from plague were recorded. The quinquennial mean death-rate of Nasik is 34·29, and there was an increase of upwards of 20 per 1,000 in 1896; the increase of deaths from fever seems to be the chief cause of rise; no case of plague was reported. In Godhra the increase in the death-rate, as compared with the mean, was nearly 18 per 1,000, accounted for by the prevalence of cholera and small-pox. In the City of Bombay the death-rate was 40·99, compared with 30·58 in 1895, and a quinquennial mean of 30·77. The death-rates from small-pox and cholera were more than twice the average, the death-rates from fever and dysentery and diarrhœa were higher than usual; while the recorded death-rate under "All other causes" was 25·18 per 1,000, against 19·51 in 1895, and a quinquennial mean of 19·21. There were 1,936* deaths recorded as due to plague, equal to a death-rate on the estimated population of 2·40 per 1,000. In short, the death-rate in Bombay was upwards of 10 per 1,000 above the normal; cholera, small-pox, fever, and dysentery and diarrhœa account for a little over 4 per 1,000 of the excess, while deaths registered as due to plague account for 2·40. Among the various sects the lowest death-rate, 17·14 per 1,000, was registered among "other classes," and the next lowest, 24·70, among Christians. The low death-rate among Muhammadans 24·48, as compared with the rate among Hindus 33·74, is accounted for by the fact that the former are about one-fourth as numerous as the latter in the Presidency generally, while they are nearly four times as numerous in the districts of Sind where registration is most defective. As compared with 1895, deaths registered were more numerous in the first eight months, particularly in February, and less numerous in the last four months of the year. The highest mortality occurred in July and August, and the least in October and November. Among male infants the death-rate per 1,000 living was 194·32, and among females 164·47; the corresponding figures in 1895 were 191·04 and 161·92. Among boys and girls between one and five years of age the rates were, respectively, 56·67 and 53·06 per 1,000, against 53·56 and 50·99 in 1895. There was some divergence from the normal relation of the death-rates among the sexes in the various age periods. From 5 to 10, 10 to 15, and 15 to 20 the female death-rates were the higher; from 20 to 30 and 30 to 40 the male rates were slightly, and from 40 to 50 they were considerably, the higher. Between 50 and 60 the female death-rate was the higher, after which the male rates were the higher.

Burma.

The area under registration comprises the whole of Lower Burma, except the districts of Northern Arakan, Salween, and portions of the districts of Bassien, Toungoo, and Thayetmyo, and the population concerned, as determined by the census of 1891, is 4,514,773. In Upper Burma in only four towns, Mandalay, Yamethin, Pyinmana, and Myingyan, with an aggregate population of 227,310, are vital statistics registered, but it is intended to extend the system of municipal registration adopted in Lower Burma to all the towns. Slight changes in the areas and populations under registration have been made, but not of sufficient importance to require special mention. A change, which is important, has, however, been made in the rural areas. Prior to 1896 the returns for these areas were compiled by townships, but it was found that these units were too large, while village units again were too small; it was decided to adopt the police-station area as a unit, and the rural circles accordingly now correspond to the police-station areas. In most municipalities and towns registration is carried out by headmen and elders of quarters. In some towns special paid registrars have been engaged, and in villages the work is entrusted to the headmen. The provincial Sanitary Commissioner considers that the new rules for the collection of the statistics introduced in 1897 are theoretically perfect, and anticipates marked improvements in results when they have been brought into working order throughout the province. Meanwhile, it is satisfactory to note that the improvement in the registration of vital statistics discernible in recent years has been more than

* Report of the Municipal Health Officer.

maintained, and that the birth and death ratios are the highest on record. The total number of births registered was 145,688, against 131,147 in 1895, and the ratio per thousand of the population was 32·27, as compared with 29·04 in the previous year, and 25·65 the quinquennial mean.

The highest district birth-rates were 42·84, 41·27, and 40·54 per thousand recorded, respectively, in Pegu, Sandoway, and Tavoy; while the lowest were 28·59, 28·46, and 17·91 recorded in the districts of Thaton, Amherst, and Rangoon town. The population of the last is of course urban, and the rate recorded, as in the cases of the other considerable maritime towns of Akyab (13·97) and Moulmein (24·63), was below the urban average (25·17). As the Sanitary Commissioner explains, one of the main causes in determining the low birth-rates in the larger towns is the deficiency of the females in the population. The excess of males is very great in Akyab and Rangoon. This excess is not quite so marked in Bassein and Moulmein; in the former, however, in which the proportion of males is slightly the greater, the birth-rate was 35·62, or nearly 12 per 1,000 higher than in the latter. In only nine of the 35 towns are the female populations higher than the male; these towns are all small, but in only three, Tavoy, Mergui, and Allanmyo, are the birth-rates higher than the provincial average, while in two, Ramree and Thônzé, the rates are lower than the average rate in towns. In the small populations of rural areas considerable fluctuations in the rates must be expected, but scarcely perhaps so great as is shown by a comparison of the rates recorded in Tantabin (73·96) and Kyeintali (70·33) with the rates recorded in Paingkyon (12·73) and Talaingdaung (8·02). In the province as a whole 107 boys were reported to have been born for every hundred girls, but there were great variations in the rates comparing even large district populations, the extreme percentages being 114 in Sandoway and Tavoy respectively, and 100 in Mergui.

The total number of deaths registered in 1896 was 106,687, against 101,160 in the previous year, and the death-rate, which in 1895 was 22·40 per 1,000, as compared with a quinquennial mean of 20·73, rose to 23·63. The highest district death-rates were 28·27 and 27·72 per 1,000 recorded in Pegu and Tharrawaddy, while the lowest were 17·89 and 16·76 recorded in Amherst and Mergui. The average urban death-rate was 28·34, ranging from 43·36 and 36·31 per 1,000 in Myaungmya and Rangoon respectively to 13·24 and 10·68 in Yandoon and Gyobingauk. In the rural circles, where the average death-rate was 22·93, the rates varied between 28·30 in Tharrawaddy and 15·01 in Amherst. The infant mortality was 235·9 males per 1,000 living and 169·44 females. Between the ages of one year and five years, 33·60 per 1,000 was the rate among boys, and 28·57 among girls. The male rates were higher than the female at all ages except between 20 and 40. Of the various sects, the Christians had the lowest death-rate (12·69), and the Hindus the highest (25·15), Burmese (23·97), Muhammadans (22·78), and "other classes" (19·77) occupying intermediate positions. The least mortality occurred in March, and the greatest during July, August, and September.

History of Chief Diseases.

Cholera.

In this report for the year 1894 an attempt was made to summarise the more important work which had been done, in recent years, towards the solution of the problem of the etiology of cholera.

In the conclusion it was stated that the best known observers in Europe were agreed that the comma of Koch is the principal factor, but that many difficulties remained to be explained; chief among these were immunity of persons and places, and the relationship to the microbe of cholera of the "cholera-like" vibrios found, chiefly in the autumn, in the waters of European rivers and elsewhere. The statement that cholera is caused by a particular vibrio must remain an assumption until the circumstances under which that vibrio is potent to cause cholera have been discovered. One of the most obvious first steps in this direction is the determination of the relations of the harmless vibrios found in river water, and much research has been devoted to this end. But as experience has grown and knowledge has deepened the explanation of difficulties appears to get further off than ever. One by one the tests which were believed to differentiate the comma bacillus of Koch have been found unreliable, until, in difficult cases, only one remains, the reaction with cholera-serum. Regarding even this test, Dunbar,* who is confident of its scientific value, says that it would be well not to affirm that all vibrios

* *Zeitschrift für Hygiene und Infectionskrankheiten*, Vol. XXI., p. 303.

which give a positive reaction are cholera vibrios. On the other hand, he states that one may be certain that any vibrios which fail to give a positive reaction with efficient cholera-serum are not the genuine vibrios of cholera.

It would appear, however, that the distinction of "cholera-like" vibrios from the vibrios of Koch is not generally difficult for the experienced observer; and, in Germany, the presence of real vibrios in the absence of cholera is said to be very rare. This does not seem to be the case in this country, and, in England, Dr. Klein has frequently isolated genuine vibrios derived from cases where no connection with Asiatic cholera could be traced. The recent work done by Dr. Klein, although not yet sufficiently advanced to allow of an appreciation of its full significance, seems to be by far the most important contribution made of late years to the elucidation of the cholera problem.

During the time of the recrudescence of cholera in Europe in 1893, attacks of cholera or resembling cholera occurred in England, and from 53 reported cases of this kind material was submitted to Dr. Klein for examination. In his report* Dr. Thorne Thorne classified these cases as follows:—

(*a*) Fifteen, in which, in the stools or bowel-contents, flakes were found containing commas, not only in pure culture, but distributed in the "fish-in-stream" like arrangement said by Koch to be absolutely characteristic of the vibrios of cholera.

(*b*) Fifteen, in which, although examination of the stools or bowel-contents gave equivocal or negative results, cultural tests demonstrated the presence of Koch's vibrio.

(*c*) Twenty-three, in which the presence of the vibrio could not be demonstrated by any means at Dr. Klein's disposal.

The bacteriological examinations were completed in nearly all instances before the receipt of the clinical histories of the illnesses. When the latter were compared with the results of the former, it was found that the 30 cases (*a* and *b*) in which vibrios had been demonstrated presented, almost without exception, the clinical features of Asiatic cholera, and all but two were fatal. In only a minority of instances, however, had the persons attacked been residing in localities where unmistakeable cholera had already manifested its presence, or where it made its appearance soon afterwards. In more than half of the cases, indeed, the circumstances were such that, but for the bacteriological evidence, the seizures would have been considered to be cholera *nostras*. Of the remaining 23 cases (*c*), in six the materials submitted were not in a state to admit of the detection of vibrios even if present. Little more half the 23 attacks proved fatal, and, when fatal results did ensue, death was often greatly delayed. In a few of the attacks, however, the disease was not to be distinguished from Asiatic cholera, and the antecedents were such as to tend to the presumption that they were cases of that disease. Further, Dr. Klein found the behaviour in culture media of some of the vibrios which he succeeded in cultivating to differ from the behaviour of Koch's vibrio, and was disposed, therefore, to conclude that several microbes might be included under the term "Koch's vibrio."

Commas, then, were found in cases which, clinically and from their antecedent circumstances, seemed to justify the exclusion of cholera from the diagnoses; and cases occurred in which, clinically and otherwise, the presence of cholera was indicated, but the commas were absent. Moreover, there was variation among the vibrios which were insolated. In view of these facts, the Local Government Board directed that further examination should be made into the occurrence of cases of suspected cholera.

In 1894 and 1895, Dr. Klein examined materials from 29 such cases.† The localities where the attacks occurred were widely separated, but in some of them cholera had been present in 1893. Several of the seizures were clinically indistinguishable from genuine cholera, and, in some instances, the localities and circumstances were suggestive of their relation to cases of that disease. In no single instance, however, were Koch's vibrios found after the most diligent search. But other microbes were present in great abundance, as it were in place of the vibrios. These microbes were the *bacillus coli* and the *proteus vulgaris*. An analysis of 28 cases—for of one no details are given—shows that in 16 the *bacillus coli* was isolated alone in pure culture, in five the *proteus* alone, while in seven both microbes were present. In three of the seven the *bacillus coli* predominated, in two the *proteus*, and in two the predominating microbe is not stated. Not only did

---

* Reports and Papers on cholera in England in 1893; with an Introduction by the Medical Officer of the Local Government Board.

† Twenty-fifth Annual Report of the Local Government Board, 1895-96. Supplement containing the Report of the Medical Officer, Appendix B, No. 1.

these bacteria seem to replace the vibrios of Koch, but, in some instances, the *bacillus coli* was distributed in the epithelial flakes in the "fish-in-stream" arrangement formerly believed peculiar to Koch's vibrio and absolutely diagnostic of cholera. The cases in which this arrangement was found were chiefly those in which Asiatic cholera was most closely simulated, not only clinically but in the naked eye appearances on *post-mortem* examination, and were mainly derived from localities where cholera had been present in 1893. "In a word," writes Dr. Thorne Thorne, "they differed from that disease solely in the circumstance that the "predominant micro-organism, which exhibited in the intestinal flakes the 'fish-in-stream' "arrangement, was not Koch's vibrio but *bacillus coli*." It may be noted that in one instance the *proteus* was present in streaks and lines in the hyaline matrix of the intestinal flakes.

Whatever may be the significance of these observations, researches, so far as they have gone, seem to indicate that, when genuine cholera exists in the neighbouring European countries, cases of disease, clinically resembling Asiatic cholera, which occur in England, are, generally, distinguished by the presence of vibrios, while, if there is no genuine cholera in the neighbourhood, vibrios are replaced by other microbes in similar cases of disease.

In England the procedure adopted on the occurrence of cholera or cholera *nostras* differs according to the variety of microbes detected. If vibrios are discovered in the stools or bowel-contents in a suspicious case, Asiatic cholera is administratively held to be present, and extreme measures of precaution are taken. In India we have long been familiar with the necessity for treating sporadic cases differently from epidemic outbreaks; but the presence of "administrative" cholera is decided, not on bacteriological, but on clinical and epidemiological evidence. When a suspicious case of illness occurs among a body of men, the building in which the case occurred is evacuated and the men are segregated; if a second case occurs among the same body of men, they are again moved; and, if a third seizure takes place within a week of the first, the men are moved from the station to a preparatory camp. The procedure in India has been blamed in some quarters on what seems to be very insufficient grounds. It must be admitted, if vibrios are alone the potent factors in the causation of epidemic cholera, that the European method of determining, by a bacteriological examination, whether genuine cholera is, or is not, present, has the appearance, not only of being more scientific, but of being more reliable than the Indian method. But it must be remembered that all the conditions are essentially different. In Europe it seems that the presence of "cholera-like" vibrios in water is not common, except at certain seasons of the year, while the presence of vibrios in the intestines, in the absence of cholera, is very rare. In India, it would appear, that vibrios are very common in water,* while sufficient facts have not yet been recorded to enable us to say whether they are frequent or infrequent inhabitants of the human intestine, or whether they or other microbes are generally present in sporadic cases of clinical cholera.

Single cases of cholera form no inconsiderable proportion of the total number of attacks among troops and in prisons in India, and it is evident, if vibrios are invariably present, that it would not be an advantage to take the extreme measures of precaution necessary on the occurrence of epidemic cholera, whenever they are found. Again, the functions of the administration in Great Britain and India are different. Great Britain has, happily, for many years been exempt from severe epidemic outbreaks of cholera, and the sanitary condition of most of the towns is now sufficiently good to justify the hope that the prompt adoption of measures of precaution will check an outbreak. In India no large part of the country is free from cholera for any great length of time; in the greater part of the country cholera is an annual visitant, and in some places it is continually present. Unhappily the time seems yet far distant when it will be possible to prevent epidemic cholera occurring in Indian towns, and, as yet, the only action which the administration can undertake with a reasonable certainty of success is the prevention of serious mortality when cholera breaks out in a body of men under their control.

Until we know exactly what the cause of cholera is, it is clearly impossible to remove that cause from a body of men; but we can remove the body of men from the cause. And movement, in India at any rate, is the one sovereign remedy; it rarely fails, and when it does fail, the failure can, generally, be easily traced to the neglect of reasonable precautions.

* An enquiry into the relative frequency of vibrios in Indian waters, with reference to the prevalence of cholera in different parts of India, would be of great interest. Are vibrios always present in endemic areas and absent from, say, the Punjab, except in cholera seasons?

Experiments in India.—Two experiments in cholera prophylaxis are being carried out on a great scale in this country. One, suggested by Mr. Hankin, aims at the destruction of the cause of cholera as near to its source as possible, the other, devised by M. Haffkine, is intended to render the human system immune to the disease, by rendering it capable of destroying the cause when it reaches the body. The first method depends on the belief that cholera is commonly, if not always, water-borne ; the second, on the belief that a particular vibrio is the principal factor in the disease.

Mr. Hankin's method—Mr. Hankin recommends that, on the outbreak of cholera, the sources of the water-supply of the people living in the neighbourhood should be treated as far as possible with some chemical disinfectant, preferably permanganate of potassium. There seems to be some misconception abroad as to Mr. Hankin's suggestion, and he has been charged with bringing forward as a discovery a well-known chemical fact. It is quite true that the use of alum to clear polluted waters has been known for a very long time, and that, so far back as 1859, manganates and permanganates were shown by Hofmann to be valuable disinfecting agents, while their general application for such purposes was made popular by Mr. Condy. But Mr. Hankin's suggestion is the application of the well-known properties of chemical agents to the prevention of cholera by endeavouring to destroy the cause of the disease near its source, and, as such, seems to be absolutely new. What remains to be proved is the effect of the measure ; and there are obviously great difficulties to be encountered in proving whether it is efficacious or not. On the one hand, epidemics of cholera are prone to sudden cessation, from unknown causes, and, on the other, when the disinfectant is employed, sources of infection may remain, either overlooked altogether or insufficiently disinfected. Epidemics in villages cannot be arranged, and it must be a long time before the number of accumulated facts is large enough to establish conclusions. As yet only opinions are available, and, so far as they are of any value, they are distinctly in favour of the procedure, though the evidence, it must be confessed, is conflicting.

Anti-cholera inoculations.—M. Haffkine's inoculations were carried on in 1896, in Bengal, at first under M. Haffkine's own superintendence, and subsequently by Surgeon-Captain J. C. Vaughan and two Assistant Surgeons, acting under his general supervision. The total number of persons inoculated in Bengal, exclusive of Calcutta and its suburbs, was 4,413, most of whom were coolie emigrants proceeding to Assam.

The distribution of cholera in India.—The total number of deaths recorded as due to cholera throughout India and Burma in 1896 was 471,779, a mortality greatly in excess of that of the preceding year, when 313,420 deaths were recorded, but considerably lower than in 1894, when the number was 521,975. Except in Assam, Burma, Ajmere-Merwara, and Mysore, the numbers of cholera deaths in all the provinces were higher than in 1895, and it may be noted that, in spite of the lower aggregate number of deaths, the mortality was higher than it was in 1894 in all provinces, except Bengal, the North-Western Provinces and Oudh, Hyderabad, and Burma.

In the following statement the number of deaths registered in the various provinces in 1896 are compared with the numbers registered in each of the preceding 19 years :—

Ajmere-Merwara ...	0·02	1·17	0·06	0·01	0·5	0·13	0·23	June & August.

The number of deaths registered as due to cholera in Bengal in 1896 was 226,824, equal to a death-rate from that cause of 3·19 per 1,000, as compared with 2·49 in 1895, and 2·91 the quinquennial mean. The increase is ascribed, generally, to the concentration on account of the deficient rainfall of the bad water-supply of the people. The cholera death-rates were highest in the districts of Muzaffarpur (8·78), Balasore (7·72), Howrah (6·73), Nadia (6·52), Darbhanga (6·24), 24-Parganas (5·83), Khulna (5·72), and in the City of Calcutta (5·06). In all of these districts, except Muzaffarpur, the prevalence of the disease was ascribed to deficient and polluted water-supplies. In Muzaffarpur, however, the disease was much less prevalent in the south and centre of the district, where the people are described as having recourse for drinking purposes to stagnant puddles, than in the north of the district, where the water-supply was comparatively abundant. The Sanitary Commissioner accounts for these curious facts as follows :—

"That" (*i.e.*, greater severity where water most plentiful) "may be the cause of its greater virulence "there in a year in which there was not enough rain to flush and purify the tanks and wells. It "may be imagined that cholera once started in such a locality, and the habits of the people being "what they are, all the water supply would soon become polluted or impregnated with the cholera "germs, and then it is easy to account for the rapid spread and virulence of the disease."

This explanation is quoted, apparently with approval, in the resolution by the Local Government, but it is difficult to follow. The disease was prevelant in every registration circle in the district, and if we are to accept a deficient polluted water-supply as the cause of cholera prevalence in the other districts, the explanation given does not render it apparent why it should be regarded as a comparative protection in part of Muzaffarpur. It may, however, be noted that the localities named in which the cholera death-rates were highest are, except Darbhanga, in Bengal proper and Orissa, and that, with the exception of Darbhanga, the greatest prevalence of cholera in them occurred before the end of May. In Darbhanga the disease was most prevalent from April till July ; in Muzaffarpur, from April to September.

Not only was the mortality of the year very high, but the disease was very widely spread, and only 34 of the 701 registration areas were entirely free from it. The rural mortality was 3·09 per 1,000, much lower than the urban, which was 5·14. In only five towns, Darjeeling, Kurseong, Kishanganj, Lohardagga, and Daltonganj, was no death registered, although in a good many there was only a single death. In the province as a whole the disease was most severe in April, May, and June. In Bengal proper and in Orissa, the months of greatest prevalence were March and April ; in Bihar, May and June ; and Chota Nagpur, where cholera was comparatively less prevalent than elsewhere, May, June, and July. The periods of least prevalence in the province, as a whole, were October and November ; in Bengal proper, August and September ; in Bihar, October, November, and December ; in Orissa, October and November ; and in Chota Nagpur, October, November, and December.

The number of deaths ascribed to cholera in Assam in 1896 was 17,042, equal to a death-rate of 3·39 per 1,000, against 3·78 in 1895, and 3·97 the average of the previous five years. In the Surma Valley the disease was much more prevalent than in 1895, but in every district of the Brahmaputra Valley, except Nowgong, the death-rates were lower. In Nowgong, where the death-rate in 1895 had fallen to the comparatively low figure of ·91 per 1,000, it rose in 1896 to 4·22. Following Nowgong, the districts in which the highest rates were recorded were Sylhet 3·86 and Lakhimpur 3·67 ; while in Kamrup, where the highest rate was registered in 1895, the mortality fell to 1·49, the lowest in the province. The average cholera death-rate in rural areas was 3·35, much lower than the towns, in which the average was 5·50. The excessive urban rate was due to the deaths of coolies landed at the depots at Tezpur (where the enormous cholera death-rate of 26·18 was registered), Dhubri (22·38), Silchar (14·09), and Gauhati (9·18). If these deaths, aggregating 302, are excluded the urban death-rate from cholera is reduced to 2·85, considerably less than the provincial average. Only three small towns escaped altogether, Mangaldai, where in 1895 16 deaths yielded a cholera death-rate of 22·89, Jorhat, and North Lakhimpur.

In the tea-gardens the estimated mortality was 4·64 per thousand. The facts that the sanitation of the gardens is generally much better than in the villages, and that the incidence of cholera is more severe in the latter than in the former, lend the appearance of probability to the belief, frequently expressed by civil surgeons, that the mortality from cholera in tea-gardens is due to the introduction into them of the disease by immigrant coolies. It is pointed out in the resolution of the local adminstration that the cholera death-rate in tea-gardens appears much higher than it really is, as it is calculated on the census population of 1891, and since then the garden population has increased by nearly

30 per cent. Calculated on the actual population, the cholera death-rate in the gardens is about 3·58 per thousand. It is said that the majority of deaths from cholera in the gardens occur during the height of the immigration season, whereas the greatest prevalence of the disease in the province generally does not shew this coincidence. It would be of interest—and might furnish data on which to base preventive measures—if details were obtained shewing whether cholera is confined to new comers, who presumably contract the disease *en route* to the gardens, or whether, and in what gardens, the disease spreads among the resident coolies. In connection with the mortality of coolies on their journey from India to Assam, Surgeon-Major Campbell was deputed near the end of the year to enquire into the conditions of the journey. He has submitted an interesting report. Effect has already been given to some of his suggestions, and others, from which much benefit may be expected, will be adopted.

As usual, cholera was present in every district of the Brahmaputra and Surma Valleys, and in every month of the year. In the province as a whole, the maximum prevalence of the disease was in November and December, due to a great and sudden increase in the Surma Valley in the former month. In the Surma Valley the months of greatest prevalence were November, December, and January ; in the Brahmaputra Valley, April, May, and June.

The total number of deaths from cholera in the North-Western Provinces and Oudh was 69,147, and the death-rate was 1·47 per 1,000. This, although higher than in 1895, when the rate was 1·10, is considerably lower than the quinquennial mean of 2·58. The death-rates were highest in Jhansi (8·95), Banda (5·88), Bareilly (4·15), and Naini Tal (4·10). No district escaped entirely, but only 13 deaths were recorded in Budaun, 11 in Etawah, and two in Mainpuri. The rural death-rate was 1·46, as compared with 1·58 in the towns. Among the larger towns, Jhansi (7·30), Aligarh (4·54), Ghazipur (4·22), Muttra (3·96), Benares (3·02), Fyzabad-Ajudhia (2·81), and Jaunpur (2·40) suffered greatly. The disease was very severe in some of the smaller towns, among them Lalitpur (15·86), Sahtawar (11·72), and Shahabad (11·16). There was little cholera in the provinces in January and February, but there was a rise in the number of deaths in March, and a great increase in the mortality in April. In May the number of deaths reached 12,480, due principally to a very severe outbreak in Banda. In June there was a decline, and in July this was more than maintained. In August the number of deaths again increased, until the maximum of 12,926 was reached in September, after which the number fell off, and only 226 were recorded in December. Regarding the epidemic in Banda Dr. Thomson writes :—

> " The most violent outbreak was that in Banda. It broke out with great severity on relief works " and the district was visited and reported on by both Doctor Hutcheson (who had temporarily " returned to these provinces) and myself. High as the recorded mortality is, it probably falls short " of the truth, for great numbers of people died *en route* to their homes, and of these no statistics " could be obtained. The frightened people adopted a procedure which was probably the best under " the circumstances, and ran away from the infected areas. Any one who has seen how cholera can " spread and destroy in such a community will understand how little can be done in practice to stay " the disease when once it has thoroughly seized on the people. The water-supply is generally the " most active agent in the dissemination of the disease. In Banda the supply was carefully protected " as far as possible, but water was scanty and the wells were few.
>
> " The outbreak, though so violent, did not last long. The deaths rose from 67 in April to 3,037 in " May, declined to 989 in June, and sank to 45 in July.
>
> " The history of this outbreak, and termination appears to indicate that, in the event of cholera " appearing on large relief works, the best procedure is to immediately quit the infected locality and " to break up the gangs into as small and manageable units as is possible, and consistent with organiza- " tion and discipline. The water-supply must be most rigorously guarded—search parties going in " front of the moving gangs to select and protect the wells."

There was no outbreak of epidemic disease at the Hardwar, Dadri or *Magh mélas*.

In 1896 the total number of deaths registered as due to cholera in the Punjab was 5,146, equal to a death-rate of ·25 per 1,000 of the population, as compared with ·03 in 1895, and ·85, the mean of the preceding five years. Although the disease spared only nine of the 31 districts, it was severe only in Rawalpindi, where the death-rate reached 2·81 per 1000 ; the next highest rates having been ·77 in Kangra and ·73 in Dera Ghazi Khan. The distribution of the earliest reported fatal cases is interesting. The province was free from the disease until the 14th of April, when a fatal case occurred in the district of Ludhiana. This was an isolated case, for no other death was reported in the district until June, when 14 occurred. On the 1st of May a fatal case was reported in the rural circle of Khanpur in the extreme northern district of Hazara ; on the 3rd May a death was reported in Tarn Taran in Amritsar, and on the 5th May another case terminated fatally in Ghazi in Hazara.

The next three first fatal cases occurred in the extreme south-east of the province—on the 9th May in Butana in Karnal ; on the 10th in Gohana in Rohtak ; and on the 11th in Hodal in Gurgaon. On the 12th May a fatal case was reported in Sirhali Kalan, a rural circle in Amritsar, and on the 13th a death was reported from the rural circle of Rawalpindi. Between the 13th and the 18th deaths occurred in 18 registration circles in the Rawalpindi district ; on the 27th May there was a death in the town of Hazro ; and on the 6th June, in the rural area of Pindigheb. Only three circles of registration in the Rawalpindi district escaped, namely, the town circles of Pindigheb and Attock, and the rural circle of Makhad. The spread of the disease is ascribed by Dr. Roe to an outbreak at the Nurpur fair, a religious assemblage at a place about eight or nine miles from the town of Rawalpindi. The fair began about the 8th of May ; cholera broke out severely on the 12th, and, as we have seen above, fatal cases occurred throughout the district between the 13th and 18th of May.

The average mortality in rural areas was ·26 per 1,000, nearly twice as high as the ratio in towns, which was ·14. The only town that suffered severely was Rawalpindi, where 3·63 per thousand of the population died of cholera ; the next highest ratios having been ·52 per 1,000 recorded in Peshawar, and ·36 registered, respectively, in the towns of Rewari and Palwal, in the district of Gurgaon. Seasonally, the disease reached its maximum of 1,245 deaths in May, and there was but little diminution until August, when the number of deaths fell to 845. After this the number of deaths declined steadily to 547 in September, 231 in October, 33 in November, and 1, an isolated case in Delhi, in December.

The number of deaths ascribed to cholera in the Central Provinces in 1896 was 52,985, equal to a death-rate of 5·58 per 1,000, as compared with 1·63 in 1895, and 1·78 the quinquennial mean. This enormous death-rate has been exceeded only in 1869, when the rate computed was 10·50 per 1,000, and in 1889, when the death-rate was 5·96. Cholera was present in every district in the province ; the death-rates ranging from 15·75 in Mandla to ·68 in Burhanpur. In twelve of the twenty districts the rates were lower than the provincial average, and in five, Narsinghpur, Hoshangabad, Nimar, Burhanpur, and Betul, they were lower than the average in these districts during the preceding five years. In five of the districts, Mandla (15·74), Bilaspur (10·99), Damoh (9·57), Seoni (9·48), and Raipur (9·00), the millesimal death-rates were nine or more. In Mandla there were 5,344 deaths, and the disease lasted from the middle of March until October. The spread of cholera is said to have been facilitated by the limited water-supply, while the low general health of the people, the poorer classes of whom were existing on roots and forest herbs, rendered them an easy prey. In Bilaspur it is stated that there is clear evidence of cholera having been imported by pilgrims. The disease appeared in three different places almost simultaneously, namely, the village of Mahwadi, Bilaspur town, and Baloda. The first cases were those of three coolies who returned from the *Magh méla* at Allahabad to the village of Mahwadi in the Janjir circle on the 31st January and died the same day. In Bilaspur town three tea-garden coolies of a batch of twelve, residing in the jail compound, died of cholera on the 1st of February. In the Baloda circle the first case is said to have occurred on the 4th February, in the person of a woman who had just returned from the *Magh méla*. On the 4th February, also, cholera broke out in the towns of Mungeli and Ratanpur, places 35 miles apart, the former in the west and the latter in the north of the district. The first victims, in both cases, were " residents who had recently been absent " from their homes. On the day of the outbreak, however, and for several days previously, " many pilgrims returning from Allahabad had passed through Mungeli and Ratanpur." Dr. Hutcheson guardedly endorses the theory of importation from Allahabad in the following terms :—

" The concurrence of the outbreak at Mungeli and Ratanpur with the return of these persons who " halted at both these places would lead one to think that it was more than a mere coincidence. With " regard to the garden coolies, many of them coming to Bilaspur had travelled by the Kutni Branch " of the Bengal-Nagpur Railway, that is, by the same route by which the returning pilgrims travelled, " and among whom at the time cholera was prevalent. Both coolies and pilgrims must have halted " for some time at Kutni, and the water-supply of this place is obtained from a large open masonry " well, some 20 yards from the station. It is quite possible that the first outbreak of cholera among " the coolies was caused by ' contact or communication with the pilgrims.' "

Now, while there is no reason to doubt that the first sufferers were pilgrims or persons who had been in contact with them, it is difficult to accept the theory that they contracted cholera at the *Magh méla*, for, as we have seen, there was no outbreak at that festival ; indeed, there were only two deaths in the Allahabad district in January (the earlier on the 29th), and only 39 during February. If Kutni was the centre of dissemination, cases

should have occurred in the Murwara district in which it is situated simultaneously with the outbreak in Bilaspur, but the first fatal case in Murwara was reported on the 14th February, nearly a fortnight after the occurrence in Bilaspur.

In Damoh the severity of the disease, which is stated to have been imported from Saugor, was attributed to great scarcity of pure water. The disease is said to have been brought into the district of Seoni by beggars, one of whom died of cholera and was left unburied on the banks of a *nala* whence the water-supply of the village of Bareylee Kalan is taken. "The disease spread from this village rapidly." Regarding its introduction Dr. Hutcheson writes :—

"It was one of the worst epidemics the district has experienced. The suddenness with which the "disease spread, and its almost simultaneous appearance in circles widely separated, show that there "was some widespread local predisposing cause apart from importation. The disappearance of the "disease on the onset of the monsoon, and the extreme dryness and the high temperature of the "preceding months, seem to indicate that the predisposing cause was largely meteorological."

In the Raipur district the first case was that of a *malguzar*, who was attacked at Kutni station when returning from a pilgrimage to Allahabad. "The disease broke out "simultaneously in four outposts, and mostly among pilgrims." In this district, and in Bilaspur, the water-supply of the people is mostly taken from tanks which are filled by surface drainage. In a year of deficient rainfall these tanks are, of course, more than ordinarily polluted.

It would appear from the seasonal distribution of the deaths that the concentration of the polluted water-supply was a very favouring agent to the distribution of cholera in the province generally. In January there were only 29 deaths in three districts ; in February six districts had been attacked, and there were 829 deaths ; in March the deaths in fourteen districts aggregated 2,879 ; in April there was an enormous rise to 8,407, and only four districts were free from the disease ; in May the increase was maintained, and every district, except Burhanpur and Sambalpur, contributed fatal cases, of which 12,935 were registered. In June the maximum of 14,000 deaths was reached. In the beginning of July rain was general, and the number of deaths fell to 6,384. In August heavy rain fell, and the deaths declined to 4,931. In September the decline continued, and 1,816 deaths were registered, in October 424, in November 143, and in December 208.

The average death-rate in rural areas was 5·67 per 1,000, considerably higher than the urban average, which was 4·61. In some of the towns, however, the death-rates were enormously high—in eleven over 10 per 1,000. The highest death-rates were registered in Lakhnadon, a small town in the Seoni district, where 83 deaths yielded a death-rate of 41·05 per 1,000 ; in Mungeli 190 deaths, death-rate 39·95 ; in Damoh 382 deaths, death-rate 32·50 ; in Drug 124 deaths, death-rate 29·89 ; in Mandla 20·57 ; in Bilaspur 15·74 ; in Arung 15·42 ; in Khurai 12·91 ; in Sailu 11·36 ; in Umrer 10·94 ; and in Hatta 10·17. On the other hand, seventeen towns, including Burhanpur, escaped altogether, and in others the death-rates were comparatively low. Raipur, it is stated, was protected by its water-supply. In that town there were 71 deaths, equal to a death-rate of 2·99, as compared with the district rate of 9·10. The first few cases that did occur are said to have been due to importation, and the remainder to the contamination of a tank.

The number of deaths from cholera in Berar was 12,264, and the death-rate was 4·3 per 1,000, as compared with 4·2 in 1895, and 1·8 the average of the previous five years. The greatest mortality, as in 1895, occurred in Basim, where the death-rate was 7·3 per 1,000. The next highest rate was 6·9 recorded in Wun, and in the remaining districts the rates ranged between 4·2 in Amraoti, and 2·5, respectively, in Ellichpur and Akola. The average rate in rural areas was 4·2, against 5·3 in the towns. Among the latter five escaped, Karanja, Buroor, Sendurjana, Pusla, and Mehkar. The cholera history of these five towns during the last three years is remarkable. In 1894 eighteen of the thirty-seven towns in Berar were free from the disease ; among those that escaped were Karanja and Mehkar, while in Sendurjana and Pusla the two highest cholera death-rates in the province, 18·9 and 15·8 per 1,000, were recorded, Buroor coming fourth with 10·3. In 1895 only eleven towns escaped, including Karanja, Buroor, Sendurjana, and Pusla ; in Mehkar the death-rate was 5·3 per 1,000. Dr. Little drew special attention to the immunity of Sendurjana, Buroor, and Pusla in 1895, and it might be instructive to attempt the discovery of the reason of their continued immunity. As compared with the epidemic of the previous year cholera was more widespread, but, save in the district of Amraoti, less intense. As in 1895 the seasonal mortality was abnormal, but the abnormality was more pronounced. Usually the mortality from cholera in Berar is at a minimum in the earlier part of the year, rising towards the end of the hot weather to a maximum in August and September, after which the mortality suddenly falls, and then

steadily declines until the end of the year. In 1895 the disease was unusually prevalent in the earlier part of the year, and the provincial maximum was attained in July: though in Wun the maximum was reached in March, and in Amraoti and Ellichpur in May. In 1896 there was no great prevalence of cholera in January and February, but the number of deaths in March was far above the average, and the maximum was reached in April; there was a falling off in May, and a very remarkable fall in June. In July the number of deaths rose to the level of the mortality in May; in August there was a great drop, and after that a steady decline until the end of the year. It seems possible that the early rise was due to unusual contraction of the water-supply; and that the decline in June was due to the rainfall in that month. But an unusual seasonal distribution of mortality was not confined to cholera.

"This unusual seasonal incidence was not peculiar to cholera alone, but under other disease causes, "it will be seen that the months of March, April, and May were the months of highest mortality, "which points to some general and unusual influence throughout the province affecting the public "health.

"The general cause or causes which exercised this baneful effect on the health of the people is, "however, a problem impossible to definitely solve in the present state of our knowledge."

The recorded number of deaths from cholera in Madras in 1896 was 47,847, equal to a death-rate of 1·5 per 1,000, as compared with ·6 in 1895, and 1·6 the quinquennial average. No district escaped the disease, although in South Kanara, the Nilgiris, Kistna, Nellore, and Madras the mortality was comparatively slight. The highest district rate was 5·4 recorded in Coimbatore; this was followed by 4·7 in Bellary, and 3·5 in Anantapur. In Bellary, Malabar, South Arcot, and Tanjore deaths were recorded in every month of the year. The rural death-rate was much lower than the urban, 1·4 per 1,000, as compared with 2·3. Seventeen of the towns, including Cannanore, Nellore, Mangalore, Musulipatam, and Guntur, escaped altogether, and in others there were only a few deaths. On the other hand, some towns suffered very severely. In Kilakarai, a town in Madura, of rather more than 12,000 inhabitants, there were 751 deaths, equal to the enormous death-rate of 60·6 per 1,000. In Ambur in North Arcot 248 deaths yielded a death-rate of 23·4. In Vaniyambadi in Salem there were 289 deaths, and the death-rate was 18·2. In Tiruppattur in the same district 267 deaths gave a death-rate of 16·2. In Cochin (10·8), Tadpatri (10·0), Palamcottah (9·8), Berhampur (8·9), Karur (8·6), and Tinnevelly (6·5) exceptionally high rates were registered. By far the greatest mortality (17,999 deaths) occurred in December, followed by November (5,961) and September (5,898); the smallest number of deaths were recorded in March (274) and April (322).

There were 49 deaths from cholera in Coorg, and the death-rate was ·28 per 1,000, as compared with a quinquennial average of ·09. Six deaths in Virajendrapet and five in Fraserpet yielded an average millesimal death-rate in the towns of ·71, as compared with ·24 in rural areas. The deaths occurred in July (11), August (27), September (6), and December (5).

There were 35,404 deaths registered as due to cholera in the Bombay Presidency in 1896, and the death-rate, which in the previous year was only ·47 per 1,000, rose to 1·88, or ·58 per 1,000 in excess of the quinquennial mean. In the province of Sind there were only 5 deaths recorded in Thar and Parkar in June; but all the other districts were affected, although the epidemic was severe only in Bijapur (death-rate 6·59 per 1,000), Pooña (5·97), Ahmednagar (3·26), Belgaum (3·10), Satara (3·03), and Kolaba (2·08). The death-rate in rural areas, 1·90, was somewhat higher than the urban rate, which, although one-third of the towns escaped altogether, was 1·71. In many of the towns the cholera death-rates were very high; notably Athni (13·06), Wai (12·06), Godhra in Ahmedebad (11·30), Godhra in Panch Mahals (9·12), Broach (8·24), Junnar (7·39), Gadag Bettigeri (6·84), Pandharpur (6·57), Nasik (5·94), and Sengamner (5·65). The greatest prevalence of the disease was in the months of May to August inclusive, with the maximum in July.

The number of fatal cases of cholera registered in Lower Burma in 1896 was 2,959, equal to a death-rate of ·66 per 1,000 of the population, as compared with 1·14 in 1895, and 1·04 the mean of the previous quinquennium. Two districts, Kyaukpyu and Mergui, were entirely free from the disease, and, except in Myaungmya (2·02), Bassein (1·99), Thôngwa (1·29), and Tharrawaddy (1·26), the district death-rates were under 1 per 1,000. In rural areas the average death-rate was ·69, against an average in the towns of ·40. Fifteen towns escaped altogether, and, except in the small towns of Myaungmya (8·88), Maubin (4·69), Lemyethna (4·10), Letpadan (3·56), Zigon (2·89), and Gyobingauk (1·00),

the cholera death-rates were low. The greatest numbers of deaths were registered in the months of July, June, and May, and the least in March and February.

Among the populations of the four towns in Upper Burma in which deaths are registered, only two fatal cases of cholera were reported, both in Myingyan.

Summary of the cholera registers.—The following paragraphs are compiled from the official reports, by the officers in medical charge, of the occurrence of cholera among bodies of troops and among prisoners.

Cholera occurred among European troops on 25 occasions and in 21 different stations. There were in all 74 seizures, of which 64 proved fatal, a case-mortality of 86·49 per cent. On ten occasions only one man was attacked, and nine of these attacks were fatal. It is of interest to note that at the time of the occurrence of three of these isolated fatal cases at Amritsar, Campbellpore, and Mandalay no cholera was reported to be present in the neighbourhood. In two instances the first attacks were attributed to the consumption of fruit. At Muttra, where there were only two cases, the two men had gone out together and obtained some fruit; the kind of fruit is not stated, but they brought it back to barracks and ate it shortly before they were seized with cholera. A native servant who is said to have eaten some of the same fruit was attacked at the same time and died in the Civil Hospital. The first outbreak at Jhansi was attributed to the men having partaken largely of melons while on their journey to that station.

Cholera appeared in 56 bodies of men belonging to the Native Army, on 60 occasions and in 38 different stations. There were 212 seizures and 137 deaths, a case-mortality of 64·62 per cent. In 24 instances the attacks were single. Among the Europeans isolated attacks were not more fatal than others, but among the natives the case-mortality in such attacks was about 12 per cent. higher than in the remainder. In a few first cases the seizure was preceded by dietetic irregularities.

The occurrence of cholera among prisoners was limited in 1896 to the jails in Bengal, Assam, the Central Provinces, and Burma. Cases of the disease occurred in 36 jails on 47 occasions. There were 163 seizures, of which 98 proved fatal, or 60·12 per cent. The number of isolated cases was 21, and the case-mortality among them 71·43 per cent. In some instances the prisoners were attacked soon after admission to jail, and, on one occasion, the prisoner was actually suffering from cholera when brought to the jail.

At Darbhanga the first attacked was a man who had been drinking water from a tank, the water of which teemed with microbes, said to be "cholera" vibrios, but no connection between the first and subsequent cases was established, nor could the origin of the latter be discovered.

The history of the outbreak at Myingyan, where 6 cases and 3 deaths occurred, is of etiological importance. There was no cholera reported in the town of Myingyan, nor in the neighbourhood. The townspeople use river water, while the prisoners used water from wells. This well-water is highly charged with salts, but is otherwise of good quality, and was carefully boiled before use. Prior to the occurrence of cases of cholera, the general health of the prisoners had been indifferent, and diarrhœa was very prevalent. After the occurrence of the first case the well was "disinfected," but other cases of cholera occurred. "When cholera persisted in spite of disinfection of the wells," writes the medical officer, "I changed to river water on the 11th of July, after that there was "a single case on the 12th, and diarrhœa began to diminish."

Among European troops diarrhœa was specially prevalent at the time that cholera occurred at Indore (2 cases of cholera, both fatal) and Poona (14 cases, all fatal): among Native troops, at Dinapore (2 cases, 1 death); Sirur (18 cases, 9 deaths); and Agar (7 cases, 4 deaths): among prisoners in the jails, at Myingyan (6 cases, 3 deaths); and Darbhanga (30 cases, 24 deaths).

The following statement shews, approximately, the number of buildings occupied by the various bodies of men attacked, and the proportion which furnished cases of cholera :—

Communities.	Number of buildings occupied by bodies of men attacked.	Number of buildings which furnished cases.	Percentage of buildings which furnished cases.
European troops	380	40	10·53
Native „	11,163	142	1·27
Prisoners	527	76	14·42

Cases of cholera occurred under very many different weather conditions, but it is not possible to directly connect any of the latter with the former in the relation of cause and effect.

In many instances it appears that the question in the cholera register with regard to importation has been misunderstood. The use of the term "imported" should be restricted to those cases in which (1) cholera is brought from a locality in which it is known to exist to a locality from which it is known to have been previously absent, and (2) in which the connection of subsequent cases with the first is clearly traceable.*

In only one instance, the Malwa Bhil Corps, at Sirdarpore, is cholera said to have been imported into, and spread in, a regiment. At the time of the outbreak no occurrence of cholera in the villages surrounding Sirdarpore, within a radius of ten miles, was reported by the civil authorities, but there was cholera at a village some 15 miles from the cantonment. "Here a feast was attended by some women of the regiment. On their "return to cantonment two were attacked with choleraic diarrhœa, and the outbreak "followed in the regiment." These women were attacked on the 21st of June and recovered; but in his account of the epidemic, the medical officer describes it as having lasted in the station from the 14th June to the 12th August. Moreover, he notes that the first case seen was admitted into hospital from a village $2\frac{1}{4}$ miles west of the cantonment. The date of the occurrence of the first case in the regimental cholera register is the 26th June, and, admitting that the women attacked on the 21st June suffered from cholera, it would appear that the disease was present in the immediate neighbourhood of the cantonment before their attack. Cholera may have been imported to the neighbourhood, but it cannot be correctly said to have been imported into the regiment.

Attendants attacked by the disease.—The following statement shews the number of persons who attended on cases of cholera, and the percentage that were attacked:—

Communities.	Number of cases of cholera treated.	Attendants.		Percentage of attendants attacked.
		Number.	Number of those attacked.	
European troops	74	287	1	·35
Native „	212	605	7	1·16
Prisoners	163	266	8	3·01

The medical officers who describe the outbreaks among soldiers do not, in any case, ascribe the attack of attendants to the fact of their attendance. It may be noted that at Sirdarpore (33 cases) the attendants suffered in proportion to their numbers twice as much as the rest of the regiment, but there were other causes than attendance that might account for this. Four of the persons in attendance during the outbreak in the Bankipur Jail (38 cases) were attacked, but the incidence of the disease among attendants was less than among the main body. At Darbhanga (30 cases) four prisoners were attacked while attending their fellows, and the medical officer was of opinion that, as the attendants were seized while actually engaged in looking after the sick in the cholera tents, the attacks were due to such attendance. Now, the percentage of prisoners attacked was about 14, while no less than 20 per cent. of the 20 prisoner attendants suffered; but five sweepers were also employed with the sick, none of whom were attacked, and their inclusion in the calculation lowers the percentage of attendants attacked to 16; while, if the nine members of the jail staff in actual personal attendance on the sick are also included, the percentage of attendants attacked falls below 12.

In this connection, the remarks of the medical officer of the 1st Battalion of the 2nd Gurkhas, regarding the protection afforded to that regiment by a good water-supply, may be quoted:—

"In the present year we have again had cholera freely imported into both battalions, but it quite "failed to take root. I consider the history of the cholera outbreaks in this regiment, and the way "they have been affected by its water-supply, as of the most supreme interest, and very complete and "valuable as one of the many proofs of the water-borne theory of the spread of the disease and the "great security and protection a really protected water-supply gives.

"Before 1892 the history of the 1st Battalion shows that it invariably suffered terribly when "cholera appeared in the Doon, so much so that some years ago the site of its lines and cantonments "had to be moved over two miles away from the city—of course at very great expense."

* *Vide* Sanitary Commissioner's Report for 1894, page 151.

The more important sanitary defects reported in connection with the occurrence of cholera in jails include—bad drinking-water at Myingyan; insufficient drinking-water at Damoh; a double water-supply at Bankura, where the prisoners preferred the water of a filthy tank in the vicinity of the jail to boiled river water; the proximity of a contaminated tank at Darbhanga; slight overcrowding at Balaghat; overcrowding in the sub-jails at Patuakhali and Khurda; great overcrowding at Damoh.

Effects of movement.—The effect of movement, when practised, was invariably favourable, not only in respect of the cessation of cholera, but on the general health. In more than one instance the weather was most unfavourable, but the health of the men improved, shewing that, granted reasonable care in the selection of a suitable camping-ground and precaution against unnecessary exposure, troops can be moved without danger and with advantage in all ordinary circumstances. Among the prisoners at Bankipur and at Darbhanga, 18 and 16 seizures respectively occurred after the moves; but in both occasions the epidemic ceased within four days after movement.

Other details regarding the occurrence of cholera.—The two cases among Europeans in Fort William are good examples of sporadic attacks in a community. On the early morning of the 29th of March, two warders in the Military Prison were admitted to hospital with the signs and symptoms of cholera. Both cases were typical, and both proved fatal on the evening of that day. There was absolutely no connection between the two warders, one of whom, an elderly man, had his meals with his wife, while the other messed with his brother warders.

The single case at Rurki is an example of "administrative" cholera. A sergeant had been for some time at Hardwar where there was cholera. On arrival at Rurki he was suffering from diarrhœa, accompanied with considerable vomiting, which persisted for four days, when he was admitted to hospital suffering from vomiting and purging, and the possibility of cholera was suspected. There was partial collapse, and moderate cramps, but no suppression of urine or secondary fever, and recovery ensued. Clinically the diagnosis was doubtful, but as the Government bacteriologist at Agra reported the discovery of the "cholera" microbe in a portion of the dejecta, the case was returned as cholera.

Small-pox.

The deaths from small-pox in 1896 in the parts of India under registration numbered 141,443, or 95,710 more than in the preceding year, the ratio per 1,000 of population being 0·65 against 0·21. The increase in ratio was general, affecting all provinces, but was greatest in the case of Ajmere-Merwara and the Punjab, which had also the highest ratios.

The mortality rose month by month from the beginning of the year up to its maximum in May, then sank month by month to its minimum in October, and finally rose again to the end of the year; and in the individual provinces the general course of the mortality curve was similar. Of the total deaths of the year, 64 per cent. occurred in the five months, March—July, and nearly 8 per cent. in December.

The following shews the mortality from small-pox in the different provincial registration areas of India in 1896, month by month:—

Statement shewing the deaths from Small-pox registered in the different Provinces by Months during the year 1896.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.		RATIO OF DEATHS PER 1,000 OF POPULATION.

The number of deaths recorded as due to small-pox in Bengal in 1896 was 13,388, or 0·19 per 1,000, as compared with the 0·18 of the previous year, and with the average of the past ten years, which was 0·15. The only district in which the disease can be said to have prevailed in an epidemic form was Patna, in which the death-rate was considerably in excess, not only of that of the previous year, but of that of the decennium. That district is very backward in vaccination, and it is to that cause, says the Sanitary Commissioner, that the high rate of mortality is to be attributed. The Civil Surgeon of Patna has no hesitation in saying that the disease was originated and spread by the practice of inoculation. Indeed, he has been assured that the Government vaccinators (of the *mali* caste) are quite willing to oblige by performing either vaccination or inoculation according to the wishes of the children's guardians. Death-rates over 0·50 per 1,000 were recorded in the districts of Patna (1·20), Cuttack (0·70), Shahabad (0·69), and Puri (0·66); in eighteen districts the rates varied from 0·39 to 0·10; and in twenty-three from 0·09 to 0·001; while in the Khulna district only there was no death. The urban death-rate was 0·31, as compared with a rural rate of 0·18. Mortality ratios of over 2 per 1,000 distinguished the towns of Raniganj in the Burdwan district, Patna in the Patna district, Deoghur in the Sonthal Perganas, Roserah in the Darbhanga district, Bhadreswar in the Hooghly district; and the rural areas of Maner in the Patna district, Aul in the Cuttack district, Khajri in the Midnapore district, Phulwari and Patna in the Patna district, and Gop in the Puri district. The number of deaths among children under one year of age rose from 1,924 in 1895 to 2,805 in 1896; and among children from one to twelve years of age from 4,707 to 7,026; and the percentage of children's death in the total small-pox mortality of all classes from 50·92 in 1895 to 73·43 in 1896.

Among the European seamen in the port of Calcutta 1 non-fatal case occurred against 9 cases with 1 death in the preceding year. Among the native floating population there was 1 death from small-pox against 5 in 1895, the respective ratios being 0·03 and 0·19 per 1,000.

In Assam there were 5,444 deaths from small-pox registered during 1896, against 3,849 in 1895, and against 2,370, the average of the five years 1890–94. The death-rate was 1·08, as compared with 0·77 in the previous year. The highest district death-rate, 4·16 per 1,000, representing 1,058 deaths, was recorded in Lakhimpur. The disease had been prevalent to a less extent in the preceding year, spreading from the town of Dibrugarh, into which it had been introduced by three passengers who came in a trading steamer from Calcutta. The next highest death-rate was registered in the Kamrup district, where 1,845 deaths yielded a ratio of 2·91 per 1,000. The outbreak began in the preceding year at the town of Barpeta, into which it was brought by a student from Calcutta. The inhabitants of Barpeta refused to allow themselves or their children to be vaccinated; and the consequence was that the outbreak was not speedily stamped out, and 60 deaths occurred in 1896. The Civil Surgeon of Kamrup states that the increased small-pox mortality was chiefly due to deaths from chicken-pox and measles having been returned as deaths from small-pox; but, as the Sanitary Commissioner points out, though deaths from measles are doubtless frequently returned under small-pox, the mortality from genuine chicken-pox cannot have been large. In the Sibsager district 1,024 deaths from small-pox were recorded, as against 37 in 1895. In nine towns there were no deaths from small-pox, and in the others the mortality ratio ranged from 5·05 at Barpeta, and 4·82 at North Lakhimpur, to 0·27 at Silchar. Among infants under one year of age there were 1,119 deaths, more than 20 per cent. of the total, and among children between one and twelve 2,914 deaths, more than 53 per cent. of the total.

In the North-Western Provinces and Oudh the lowest recorded death-rate from small-pox in the twenty-six years, 1871—1896, was 0·04 from 1,968 deaths in 1895. But in 1896 there were 42,771 deaths from small-pox, giving a ratio of 0·91 per 1,000. This is a considerable rise, and was anticipated by the Sanitary Commissioner; so large a proportion of the population being still unprotected. There are periods of exacerbation of the disease after intervals during which susceptible material has been accumulating. Considerable difficulty is experienced in persuading adults to revaccination, principally because it temporarily cripples them, and prevents them from following their usual occupations. The districts with mortality ratios higher than 2 per 1,000 were Allahabad (4·10), Unao (3·85), Bareilly (2·39); and there were 15 districts with ratios over 1 per 1,000, 9 with ratios not below 0·5, 18 with ratios over 0·05, only three with ratios under 0·05, and no district without a small-pox death. The highest ratios in towns were in Nehtor (12·86), and Kiratpur (10·05), in the Bijnor district, and in Aonla (10·10), in the Bareilly district. But the epidemic was very widespread, and 77 out of 100 principal

towns returned cases of this disease. The urban mortality was 0·86 as compared with 0·92 in the rural areas. Among infants under one year 14,410 deaths occurred, against 580 in the previous year; and among children under twelve years of age but not under one year, 26,443, against 1,329. Again, the percentage of deaths of the former class of children to the total small-pox mortality of all classes of the population was nearly 34 against 29 in 1895, and that of the latter class of children to the same, nearly 62 against 67.

A most severe epidemic of small-pox visited the Punjab during the year, the total number of deaths registered being 45,084, and the death-rate 2·19 per 1,000 of population; and it was the severest epidemic since 1879. The disease broke out in a virulent form in December 1895, and, in accordance with the experience of former years, attained its maximum intensity in May, after which there was a steady decline in mortality down to the minimum in September-October, the numbers again rising as the cold weather set in. The highest district death-rate was in Ferozepore (5·75), and the lowest in Kangra (0·05). Besides these, four districts had ratios over 4 per 1,000, five over 3, four over 2, seven over 1, four over 0·5, and five over 0·05. The districts with higher mortality were not, with the exception of Gujrat, among the best vaccinated districts of the Punjab; but the five districts with the lowest mortalities were so. The remarkable immunity of Kangra is attributed by the Sanitary Commissioner to the fact that it stands first in order of the best vaccinated districts in the province. The rural death-rate was 2·18, and the urban 2·36. In the case of towns the highest ratios were those of Kasur (9·61), and Bhera (9·30), and the lowest that of Dera Ghazi Khan (0·08). Two towns had ratios over 9 per 1,000, three over 8, two over 7, two over 6, two over 4, five over 3, eight over 2, seven over 1, eight over 0·5, and six over 0·05. Out of the 45,084 persons who died from small-pox, 13,065, or nearly 29 per cent. were children under one year of age; and 26,192, or over 58 per cent. children between the ages of one and twelve. It is evident, therefore, that many children must have been unprotected by vaccination; and the Sanitary Commissioner has taken steps to increase vaccination in the districts in which small-pox mortality was highest.

The number of deaths from small-pox in the Central Provinces was 7,747 against 6,644 in 1895; and the ratio per 1,000 of population was 0·82 against 0·70 in 1895, and against 0·25, the quinquennial mean. The disease prevailed with greatest intensity in the hottest month (May), and declined with the approach of the rains. The increase of mortality affected every district without exception, the greatest number occurring in Wardha, Chanda, Bhandara and Raipur. The highest ratio to population was that of Wardha (2·63), and the lowest that of Burhanpur (0·04). One district had ratio of over 2 per 1,000, four of over 1, eight of not less than 0·5, six of over 0·05, and one of under 0·05. The rural mortality was 0·85, and the urban 0·40. The towns with the highest ratios were Lakhnadon (8·41), Arvi (7·54), and Warora (4·29). Mohgaon was the only other town that had a ratio over 3 per 1,000 and there were 29 towns which recorded no deaths. In the 7,747 persons that died from small-pox were included 1,943 children under one year of age, or over 25 per cent., and 3,536 children between the ages of one and twelve, or nearly 46 per cent.

In Berar the total number of deaths registered from small-pox was 810, against 556 in the previous year; while the death-rate per 1,000 was 0·28, against 0·20 in 1895, and against 0·1, the quinquennial mean. As usual, the disease prevailed with greatest intensity in the three months March-May, declined thereafter, but rose again in the cold months at the end of the year. Among districts Amraoti had the highest death-rate (0.6), and Buldana the lowest (0·008). The Amraoti district ratio was yielded by 415 deaths, or more than half the total number recorded in the administration. In this connexion the Sanitary Commissioner noticed that in Amraoti influenza deaths, under the native name *kapsi matha*, were at first registered under small-pox, and that, though the mistake was remedied as much as possible, yet it probably served in some degree to raise the mortality under the head of small-pox in that district. The rural mortality was 0·2, the urban 0·7; but the disease, though more localised in towns than rural circles, was pretty general throughout the districts most affected. The towns with the highest ratios were Pathur (5·8) and Bulgaon (4·7), and the greatest number of cases occurred in the towns of Pathur and Akote. Out of the 810 persons who died from small-pox 162, or 20 per cent., were under one year of age, and 398, or over 49 per cent., between one and twelve.

The number of deaths from small-pox in Madras Presidency in 1896 was 9,410 against 5,111 in the previous year; and the death-rate was .0·29 per 1,000 of the population against 0·15 in 1895, and against 0·8, the quinquennial mean. The highest district ratio

was that of Kurnool (1·8), and the lowest that of Coimbatore (0·02). There were in all three districts with ratios over 1 per 1,000, one over 0·5, thirteen over 0·05, and five 0·05 or less. The urban ratio was the same as the rural ratio, namely, 0·3 per 1,000. The towns with the highest ratios were, in order, Vellore (5·3), Arcot, Nandyal, and Gudiyattam. Children under one year of age furnished 2,245 deaths, or nearly 24 per cent. of all the persons who died from small-pox; and children between the ages of one and twelve 3,632 deaths, or nearly 39 per cent.

In Coorg the total number of deaths from small-pox registered was 18 against 7 in the preceding year; and the ratio of deaths per 1,000 of population was 0·10 against 0·04 in 1895; and against 1·90, the mean of the quinquennium. Deaths were recorded in only 11 out of 517 villages in the province. The rural death-rate was 0·11, but there was no urban mortality. No children under one year of age died of small-pox, but five, that is nearly 28 per cent. of all the persons that died of it, succumbed between the ages of one and twelve.

In the Bombay administration there were in the year 1896 small-pox deaths to the number of 6,443 against 2,229 in the preceding year; and the ratio was 0·34 against the 0·12 of 1895, and the 0·18 of the decennium. As in 1895, and as in the five years preceding that, the disease reached its maximum intensity in April, then declined, but rose again in the end of the year. The highest ratios were in the Western and in the Gujrat Registration Districts, and the extreme district ratios were 0·94 for Khandesh and 0·01 for Sholapur and Bijapur. Five districts had ratios over 0·5 per 1,000, sixteen not under 0·05, and four under 0·05. The urban mortality ratio was 0·70, while that of the rural areas was 0·30. The highest town ratios were those of Godhra (10·55), Dhulia (3·02), and Umarkot (2·97). The total 6,443 deaths from small-pox include 1,901 of children under one year of age, or over 29 per cent., and 3,336 of children between the ages of one and twelve, or nearly 52 per cent.

There were 1,669 deaths from small-pox during the year in Lower Burma, and the death-rate was 0·37 per 1,000, as compared with 0·34 in 1895, and with 0·40, the mean of the previous five years. The disease persisted throughout the year, but was most fatal in March, May, April, and June, and least so in November, December, October, and January. The three districts of the Arakan Division, the Prome district, and the Mergui district had no small-pox mortality. The highest ratio, 1·17, was that of the Hanthawaddy district, and the lowest ratios, 0·01, that of Tavoy and that of Thayetmyo. Three of the districts had ratios of 1 per 1,000, none over 0·5, 7 over 0·05. The rural death-rate was 0·36, and the urban 0.47. The highest town ratios were 3·82 at Kyangin, and 1·13 at Rangoon. Out of the 1,669 persons who died from small-pox 247, or nearly 15 per cent., were under one year of age; 814, or nearly 49 per cent., between the ages of one and twelve. Unprotected coolie immigrants from India are reported by the Sanitary Commisioner to be a prolific field for the propagation of small-pox, and proposals for remedying the evil are now under consideration.

Plague.

In the latter part of 1896 bubonic plague appeared in Bombay. By the end of the year, 2,911 cases were reported throughout the Presidency, of which 2,219* were fatal, equal to an annual death-rate of ·12 per thousand of the population. A full account of the outbreak will be found elsewhere,† and the following paragraphs contain only an outline of the principal events which occurred in 1896.

In the Bombay Presidency, scarcity and high prices consequent on abnormal meteorological conditions determined a migration specially of the very poor people to the City of Bombay in search of work. The sanitary condition of the city itself was bad. For years past the drains have been insufficient to carry off the water brought into the city, and, in 1896, the state of drainage was rendered much worse than usual by abnormal meteorological conditions. The total rainfall, although less than the average, was abnormally distributed, and instead of falling during about four months lasted for six weeks only. In June, July, and August there was an aggregate excess of 27 inches beyond the average, and, to make matters worse, an obstruction formed at the sewage outfall during a great storm, when it was impossible, on account of the heavy sea that was running, to send men to remove it. In consequence the low-lying portions of the city

* The figures for Bombay City are taken from the Report of the Municipal Health Officer. Figures for the Presidency, outside Bombay City, are taken from the Report of the Sanitary Commissioner for the Government of Bombay.

† *The Plague in India, 1896–97.* Government of India, Home Department.

were flooded with storm-water and sewage, and in places not reached by direct sunlight the walls of houses and lanes remained damp for long afterwards, in spite of the excessive heat of the autumn. In September, instead of a rainfall of eleven or twelve inches, there was only about an inch and an half, an amount which was, of course, inadequate to wash away the stagnating impurities. October was dry and hot.

In Bombay the poor live in the most insanitary conditions, crowded together in high buildings called *chawls*. These *chawls* or tenements may run up to seven storeys, and the unit of construction is a long corridor with rooms opening on each side. In the corridor, either at one end or in the centre, is situated a water-tap with bathing-platform, and alongside it a latrine with two or three seats. The whole tenement is built up of congeries of these corridors and rooms, and contains from 500 to 1,000 individuals. The only space between each tenement is a gully sufficiently wide to admit a sweeper. In most of the corridors and rooms, either from the absence of openings or the obstruction of the existing ones, there is absolutely no light admitted and consequently no ventilation. It is stated that 70 per cent. of the population live in such houses.

The conditions in Bombay in August, then, were overcrowding of multitudes of very poor people in unventilated, damp, and filthy houses; the subsoil sodden with sewage, and the drains in many in places choked; add to this the putrefying of great quantities of food-grains in the hot moist air of flooded cellars.

The abnormal climatic features of the year had made the city very unhealthy, and in June, July, and August, the period immediately preceding the discovery of the existence of the plague, the death-rate had been high,—much higher than the quinquennial average for these months.

The high mortality during this period has been held to indicate that plague, although undiscovered, was present in the city, and there are those who believe that the disease was present in May. There certainly are two phenomena which give colour to this belief; one the existence of cases of a mysterious and fatal fever which were seen by native practitioners from May onwards; the other, the very wide distribution which the plague was found to have when its existence in the city was recognised. But the main argument, the comparatively high mortality during the monsoon months, falls to the ground in view of the fact that, although the death-rate in June, July, and August, 1896, was higher than the average death-rate during the same period in the preceding quinquennium, it was very considerably lower than in these months in 1894. In both years cholera was prevalent, in the earlier year slightly more so than in 1896, although the excess is not sufficient to account for the higher death-rate in 1894. Regarding the incidence of the mortality, the Health Officer points out that the high rate in August was due to the increase in the number of deaths among persons who were not natives of Bombay City. It is remarkable that, although the total mortality rose, the increase until the end of November was due to deaths among persons born outside of Bombay, while the number of deaths among those born in the city actually fell. Even in December, when there was an enormous rise in the total mortality, it was mainly due to deaths among outsiders.

When plague was detected, the distribution of cases indicated that it must have been present in the city for a considerable time. The failure to diagnose early cases is not extraordinary in view of the prevalence of a pneumonic type of the disease, and of the existence in Bombay, during recent years, of cases of fever with glandular enlargement.

As the date of the occurrence of the first case cannot be determined, the place of origin remains unknown. Its introduction has been ascribed to pilgrims from Garhwal who are said to have brought it from the Himalayan endemic area. In the absence of any positive evidence, it may, perhaps, be assumed that the place of origin was China; and there is possibly greater likelihood of the disease being brought from a place where it was raging epidemically than from any endemic area.

On the 10th of August, the Municipal Health Officer heard of the occurrence of two cases of fever accompanied by enlarged glands in the neck. On the 21st and 24th August, Dr. Ismail Jan Muhammad saw two cases in which the patients suffered from small glandular enlargements in the groin, lung complications, high fever and delirium. A case of bubonic fever was registered on the 31st of August. The first public announcement of the epidemic presence of the disease is due to Dr. Viegas, a private practitioner, who saw a case on the 18th of September, and diagnosed it to be plague. The existence of the disease in the city was officially intimated to the Municipal Commissioner on the 23rd September.

Whatever may be the actual date of the commencement of the epidemic, it was very widely spread in September, and before the end of that month cases occurred in no less than 21 of the 32 districts into which the city is divided. In September the effect of

plague deaths on the death-rate was very marked, and the mortality rose not only far above the mean for September of the previous quinquennium, but far above the September mortality of any of the years composing it. The excess mortality was not, however, shown as plague, for only 79 deaths from that disease were recorded, but as "fever," and among the diseases returned under the heading "all other causes," which included a very much larger number of deaths from affections of the respiratory organs than usual.

The epidemic began in Mandvi, a densely populated quarter situated immediately to the north of the Esplanade ward, and on the east of the centre of the city. It was in this ward, where conditions were very favourable for its development, that the epidemic was most severe in 1896. From Mandvi the disease spread, and in September, as we have seen, cases were discovered in 20 other wards of the city. In October five more wards were attacked, Second Nagapada, First Nagapada, Kharatalao, Mahalaxmi and Esplanade. In November the epidemic had spread to Walkeshwar, South Fort, Upper Colaba and Chowpatti; and in the beginning of December the remaining two wards, Mahim and Sewree, were attacked.

In September 135 cases and 79 deaths were reported. In October the number of cases had risen to 406, and the deaths to 313. In November the number of cases and deaths, 339 and 273, were considerably lower, a lull which raised hopes that the epidemic might speedily die out; but in December, an enormous rise in the number of cases to 1,664, with a corresponding increase in the number of deaths to 1,271, showed that these hopes were vain. The directions taken by the epidemic were generally west and north, the invasion of many districts being heralded by the immigration of rats. Dr. Weir is of opinion that the disease was carried from ward to ward by the rats, stating in support of his belief that the disease spread in the directions in which rats migrated, rather than the direction taken by the dispersing people. However this may be, the distribution of the disease appeared to follow groups of houses and was hardly ever found evenly distributed over a district. The death-rates were highest in Mandvi (308 deaths, or 8·25 per 1,000 of the population), Kamathipura (227 deaths, or 7·77 per 1,000), Middle and Lower Colaba (77 deaths or 5·65), and lowest in Upper Colaba and Esplanade, in each of which only one death was reported, and in South Fort where there were only two. It is remarkable that several of the most populous wards in the city showed comparatively very low death-rates from plague, but this may be accounted for by the dispersion of the people in the city itself, and by the flight from the city of enormous numbers. The estimated number that left Bombay in October was 20,000, and in November and December 171,500.

On the 29th September the Government of Bombay deputed their chief medical authority, the late Surgeon-Major-General Cooke, to enquire into the nature of the disease. He reported that he had seen about 20 cases of bubonic fever. Plague was officially declared to be present in the city, and the Government of India were informed. Instructions were immediately issued by the Government of India to M. Haffkine to proceed to Bombay and make a thorough bacteriological enquiry into the nature of the disease. M. Haffkine's examination confirmed the results already obtained by Dr. Surveyor and Surgeon-Captain Childe, and his report reached the Government on the 13th October. Meanwhile preventive measures were being energetically undertaken by the municipal authorities. At the time of Surgeon-General Cooke's inspection he found that sea-water was pumped through the sewers all night by means of a powerful pump, and cleansing, disinfection, and limewashing of walls were in active progress, fire-engines being employed in the work. Surgeon-General Cooke suggested that the sanitary and medical staff of the Municipality should be increased; that the sick should be segregated in hospital; that the bedding used by the sick, or found in the houses or rooms occupied by them, should be thoroughly disinfected or burned; that more complete arrangements for the carting away of filth from the sewers should be made; and that measures should be taken to secure the early detection of cases should they occur in suburban municipalities.

Before the end of September the Local Government had appointed a Committee, consisting chiefly of medical officers of the Government and private medical practitioners, of which the Municipal Commissioner was Chairman, to concert remedial and preventive measures. At the first meeting at the end of the month, Surgeon-General Cooke's proposals were considered. The late Surgeon-Major Manser insisted on the necessity for the complete disinfection of every house in which cases were known to have occurred and suggested the removal of the inhabitants of such houses to empty buildings or tents on the Port Trust Estate. The Chairman pointed out that this could not be done unless special powers were obtained from Government, and a resolution was adopted by the meeting that application for such powers should be made. On the 2nd of October wide powers were conferred by Government on the Municipal Commissioner to enable him to

take whatever action was found to be necessary to check the epidemic. The Corporation voted sums of money to defray the cost of sanitary measures, and a large additional medical staff were employed to carry out the extensive operations advised.

On the 6th of October the Municipal Commissioner issued a proclamation, under section 434 of the Municipal Act, making special provision for the removal to hospital of those infected, and for the evacuation and cleansing of infected houses. This proclamation excited the wildest terror among the people ; many fled, small riots occurred, and a great danger threatened, for the conservancy establishment became affected by the general unrest and a strike among them, which must have been attended by appalling results, was feared.

In view of these circumstances, the original orders were modified, and it was provided that the sick should not be moved if they were resident in houses in which they could be isolated in a reasonable degree, and could receive proper attention. Assurance was at the same time given that every allowance would be made by the officials of the Health Department, when compelled to enter houses, for the customs enjoined by caste rules. On the 30th of October these conditions were further modified by the statement that the foregoing notifications had been issued in view of a great increase in the number of cases of plague ; and it was further promised that no person would be removed to hospital who could be properly treated and segregated at home, and that, in any case, no action would be taken except upon the certificate of a duly qualified practitioner.

These orders virtually abolished compulsory legal segregation of the sick ; but efforts to secure isolation were continued, and it was sought to attain by persuasion what it appeared impossible, in Bombay at least, to attain by legal compulsion. Private hospitals were opened, but the people seemed to dread removal to them almost as much as to the Government hospitals ; while those residing in the neighbourhood where hospitals were established raised an outcry that their houses were being infected. It was not until December that private hospitals became at all successful.

In the meantime, the Government of Bombay by a resolution, dated the 13th October, appointed a scientific committee to enquire into the nature of the plague. Surgeon-Major Manser was appointed President, and undertook an enquiry into the treatment of plague by drugs. Surgeon-Captain Childe undertook the study of the general pathology of the disease ; Mr. Hankin, the study of the behaviour of the microbe of plague in nature ; M. Haffkine, the general bacteriology, and specially, the questions of immunity and of protective and therapeutic inoculations ; Dr. Surveyor the study of the disease in rats.

In November and December the work of cleansing and disinfecting was carried on with greatest energy ; but, aided though these measures were by the great exodus of the population, without making any preceptible headway against the epidemic, although it may be believed that, but for these efforts, the mortality would have been enormously greater than it was.

Bombay Presidency.—The exodus of the people was no doubt of great advantage to Bombay, but it was a terrible danger to the rest of the country ; many persons fled while actually suffering, and many fell sick on the way to, or after they arrived at, their destinations. The municipalities in the districts had, of course, been warned, and those on the line of rail did what they could to keep out infection by instituting medical inspection of passengers from Bombay. Inspections were attended by considerable success, but could not be effective in the absence of legal powers, and before the end of the year there had been 367 cases reported, or discovered, in 47 places in the Presidency, with 283 deaths.

There can be no doubt that the numbers of cases and deaths are much understated. Many cases were concealed, and deaths were returned as due to causes other than plague. As the figures stand, however, it may be noticed that the reported case-mortality in places outside Bombay was nearly 10 per cent. higher than in the city itself. Notwithstanding the large number of places into which the disease was introduced, in only five, one of them Bandra, practically a suburb of Bombay, had the pestilence taken root before the end of the year.

Ahmedabad was the first place outside of Bombay in which a case was reported. The first case (A), a very slight one terminating in recovery, occurred in the person of a Musalman who had been working in Mandvi, in Bombay. On the 18th September he suffered from slight glandular enlargement and fever, and on the 25th left Bombay for Ahmedabad, and was under the treatment of a local practitioner there for eight days.

On the 4th October he was seen by the Health Officer, who considered the disease from which he was suffering to be plague. The next two cases (B and C) were indigenous, and no connection whatever could be traced between them and the first case. The origin

of the infection could not be traced. One of the men had not recently been out of Ahmedabad. He was taken ill on the 28th September and died on the 3rd of October. The other had returned from Wadhwan, in Kathiawar, on the 17th September, and was taken ill after the 26th September—the exact date is not stated—and died on the 5th October. The houses of A and C were disinfected, and the hut in which B had lived was burnt. The city was cleansed. A staff was engaged to examine passengers from Bombay; arrangements made to disinfect luggage and goods at the railway station; and an isolation hospital prepared. No other indigenous case was reported before the end of the year. Nine imported cases were detected at the railway station in October; none in November; but 38 in December. Of the 50 cases which were discovered, 26 were fatal.

At Poona, from the 30th of September onwards, two medical men and four assistants were posted at the railway station to examine passengers. Four cases were detected at the station in October, one in November, and 43 in December, besides four cases in the city and one in the cantonment. The sick were isolated, but, in the absence of a law authorising compulsory measures, great difficulty was experienced in persuading the relatives and friends of the sick to allow them to be taken to isolation hospitals.

The first case at Bandra was reported on the 16th October. Isolation and other measures were recommended, but the municipal authorities were slow to move, the people opposed all measures, and plague progressed.

Sind.—The first case was reported in Karachi on the 10th of December. Karachi had defended itself against Bombay by quarantine rules, and it is remarkable that the origin of the first two cases could not be traced to Bombay or to any place outside Karachi, although most minute and careful enquiries were made.

Here the municipal authorities acted with great promptitude and gave effect to all the measures of prevention which were recommended for their adoption. Unfortunately compulsory segregation was not possible. In spite of much concealment, by the end of the year reports of no less than 63 cases and 59 deaths were received.

India, generally.—To prevent the extension of the disease to other provinces, the Government of India modified existing railway rules regarding infectious diseases so as to include plague, and instituted railway inspections at the large railway stations and important junctions; while measures of quarantine were adopted at the ports of Aden, Calcutta, Madras and Rangoon.

In all the larger towns special sanitary inspections were made, and so far as possible the towns were cleansed and put in a more favourable position to keep out plague; while isolation hospitals were got ready for the prompt segregation of persons who might be attacked. No indigenous case of plague was reported in India outside the Presidency of Bombay in 1896; but there were four imported cases in Rajputana and one in the Central Provinces.

Calcutta.—The most pressing danger seemed to be the infection of Calcutta, on account of the constant communication with Bombay, and the extremely filthy and overcrowded condition of great portions of the town. Under the orders of the local Government, a strong Medical Board was organised to deal with all matters appertaining to the prevention of plague, and special health officers were appointed to carry out sanitary surveys of Calcutta, Howrah and adjacent municipalities.

Great alarm was occasioned in October by the alleged discovery of cases of plague in Howrah and Calcutta. The cases of sickness had some clinical resemblance to slight attacks of genuine plague; but the medical men who made the diagnosis relied mainly on the discovery, in blood and serum taken from the sick, of a diplobacterium, which they believed to be the specific microbe of plague.

A closer examination of the antecedents of, and clinical symptoms exhibited by, the sick, which was undertaken by the Inspector-General of Civil Hospitals, did not support the diagnosis,—even of *pestis ambulans*: and the bacteriological enquiry, conducted at the instance of the Medical Board, by one of their members, Dr. D. D. Cunningham, F.R.S., Special Assistant to the Sanitary Commissioner with the Government of India, effectually disposed of the alleged discovery. Dr. Cunningham shewed (*a*) that the blood in which the diplobacteria were discovered had been exposed to external contamination; (*b*) that the bacteria isolated differed from each other and from the genuine microbes of plague; (*c*) that no microbes at all could be cultivated from specimens of blood taken from the suspected cases when proper precautions to avoid contamination were observed; and, finally, (*d*) that the death of an animal into which a culture was injected proved nothing, as the quantity of decomposing fluid injected was sufficient to cause death from blood-poisoning.

Dr. Cunningham, in addition, demonstrated the fact that the alleged "plague bacillus" might be discovered in specimens of the blood taken from healthy animals, if the blood was exposed to the air for a short time.

Fevers.

The total number of deaths registered under the heading "fevers" rose from 4,266,293 in 1895 to 4,578,944 in 1896, and the ratio per 1,000 of population from 19·53 to 21·05. The months of greatest mortality were March, January, and December, and those of least mortality, July, June, and May. Each of the first nine months of 1896 had more deaths, and each of the last three fewer than the corresponding month of 1895. The increase over the previous year was specially marked in March. It seems possible that the reduction in the last three months may have been due to the comparative absence of malaria in a dry year; and that the increase in the earlier months may have been due to the inclusion in the statistics of diseases then prevalent, such as influenza, chest complaints, small-pox, cholera, etc.

The greatest increase was in the Central Provinces, where also certain districts had higher mortality ratios than in any other province, ratios between 50 and 60 per 1,000. The lowest district maximum was 15 per 1,000 in Madras. Berar, Madras, and Ajmere-Merwara had fewer deaths and lower ratios than in 1895. In the North-Western Provinces the urban death-rate was higher than the rural, in Madras it was the same as the rural, while in all the other provinces it was, according to expectation, lower than the rural.

The following table may be consulted not only for this, but also for the succeeding paragraphs dealing with fevers:—

Statement shewing the deaths from Fevers registered in the different Provinces by Months during the year 1896.

Province.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total. 1896.	Total. 1895.	Ratio of Deaths per 1,000 of Population. 1896.	Ratio of Deaths per 1,000 of Population. 1895.

* Includes 15,637 deaths from *Kala Azar*. † Includes 15,894 deaths from *Kala Azar*.

Sale of Quinine at Post Offices.—In Bengal there was an increase of 3,337 parcels of quinine sold, equivalent to an increase of 1,701,870 grains. There was no constant relation between the prevalence of fever and the demand for quinine, and it was supposed that the demand was only there great where the virtues of the drug were known.

Progress in the scheme was made in Assam. From August all post offices in the Brahmaputra and Surma valleys were supplied with packages for sale, even when situated near dispensaries. Formerly quinine was sold only at post offices at a distance from dispensaries. The greatest success was attained in the Khasi and Jaintia Hills, where, owing to a great extent to the interest taken in the matter by the missionaries at work in those hills, the sales were very considerable. The agencies there employed were post offices, missionaries and the police. Arrangements have been made for selling pice packets of quinine through the agency of vaccinators from the beginning of next vaccinating season.

In the North-Western Provinces the scheme was first introduced, and that in the districts of the Meerut division, Pilibhit, and the Tarai parganas, being subsequently extended to Hamirpur and Gorakhpur. Only 260 packets were issued, but the scheme is still in its infancy.

Both the sale of quinine through the agency of lumbarders, postmasters, etc., and its gratuitous distribution through the members of the vaccination staff appear to be on trial in the Punjab, but there is as yet not much information available as to results. The Civil Surgeons of Gurdaspur and Muzaffargarh report that the gratuitous distribution is appreciated by the people. On the other hand, the Deputy Commissioner of Jhelum says that the people as a rule decline to spend their money on quinine ; and that he is opposed to gratuitous distribution on the ground that the quinine does not reach those for whom it is intended.

In Coorg the sale of 5-grain packets were introduced in January at 22 post offices, in places where there were no dispensaries. No information can be given as to results.

In Burma the scheme for the sale of 5-grain pice packets has now been working slightly over one year, and it has not, perhaps, quite achieved the success that was hoped for. The general opinion appears to be that the chief obstacle to the working of the scheme is a want of knowledge on the part of the people of the virtues of quinine, and it is only by time and by perseverance on the part of district officers that this ignorance can be removed. The distribution of vernacular handbills setting forth the advantages of quinine, and stating how and where the drug may be obtained, has been recommended. It is also proposed to provide vendors with packets at a smaller cost than at present, so as to increase their profits, and thereby their desire to sell.

The number of deaths attributed to fever in Bengal in 1896 was 1,760,225, as compared with 1,634,254 in 1895 ; and the death-rate was 24·77 against 22·99 for the preceding year, 22·14 for the five-year period, and 18·83 for the decennium 1886–95. As in previous annual reports, the Sanitary Commissioner points out that the heading " fever " covers a multitude of complaints in the mind of the village watchman, who is primarily responsible for registration, and that it is certain that numerous deaths are put down to fever which are really due to other causes ; and considers this not surprising, because it is far less trouble for the village watchman to say at the weekly muster that so many deaths occurred from fever, about which he knows there will be no special inquiry, than to return a large number of deaths from cholera and small-pox, about which experience has taught him there will be special inquiry and a call for daily returns which cause him extra trouble. Out of the 46 districts of Bengal 29 had higher mortalities than in the previous year, and all but two higher mortalities than in the decennium 1886–95. Though the year was on the whole a dry one yet it is stated that the increase of fever was natural, because the rainfall was intermittent, and the drying and wetting of the soil alternate. The heaviest mortality took place in the months of March, December, and February, in the order given, and the lightest in July, October, and September. The last four months of 1896 had decidedly lower mortalities than the corresponding months of 1895. Ten districts had ratios over 30 per 1,000, namely, in order, Jalpaiguri, Rangpur, Dinajpur, Darjeeling, Purnea, Rajshahi, Pabna, Muzaffarpur, Darbhanga, and Jessore ; and most of these belong to the notoriously unhealthy *terai*. Fourteen districts have ratios over 25 per 1,000, eleven over 20, six over 15, four over 10, and one (Puri) over 5. The rural death-rate was 25·05, the highest individual ratios of rural areas being those of Jalpaiguri and Darjeeling. The urban death-rate was, as usual, lower than the rural, being only 19·04 ; and the highest individual town ratios were those of Kumarkhali (46·22), a small town in the Nadia district, and of Roserha (37·01), a somewhat larger town in the Darbhanga district.

To the 211 admissions of the European seamen of the port of Calcutta from fever there was only one death, and that was from enteric fever. There were 31 deaths among the native floating population, giving a ratio of 1·20 per 1,000 against 0·74 in the preceding year.

Under the heading " fevers " in which the reporting agents are apt to include all diseases wherein rise of temperature is a prominent sympton, there were 101,347 deaths registered in Assam in 1896 ; and the death-rate, which was 18·39 per 1,000 in 1895, rose in 1896 to 20·18, or 4 per 1,000 in excess of the mean of the previous five years. Most deaths occurred in June and May, and fewest in April and February. All the eight months from January to August show an increase as compared with the previous year ; but, as in the case of Bengal, there was a decided diminution in the last four months. Much the highest district death-rates were those of Nowgong (36·31), where *kala azar* is very prevalent, and of Goalpara (32·98). Besides these, two districts had ratios over 25 per 1,000, one over 15, three over 10, and one (the selected areas in the Khasi and Jaintia Hills) over 5. The rural death-rate was 20·31, or excluding the hill district, 25·63 ; and the rural areas with the highest mortalities were Nowgong and Goalpara. The urban

death-rate was 14·41, the towns with the highest ratios being Mangaldai (35·77), North Lakhimpur, Barpeta, and Nowgong (25·13).

Regarding the distribution of this fatal form of fever the provincial Sanitary Commissioner writes :— Kala azar.

"During the year 15,637 deaths from *kala azar* and 85,710 deaths from 'other fevers' were "reported as against 15,894 *kala azar* deaths, and 76,465 deaths from 'other fevers' reported in 1895. "In the province as a whole 9,245 more deaths were registered from other fevers and 257 fewer deaths "from *kala azar* than in 1895. As in the previous year, very few *kala azar* deaths were registered "in the Surma Valley, in the Sibsagar and Lakhimpur districts, and in the portion of the Khasi and "Jaintia hills under registration. In the Goalpara district 298 *kala azar* deaths were reported during "the year as against 265 in 1895. In the Kamrup district, though the mortality registered under "'other fevers' was more than 50 per cent. greater than that recorded in 1895, the increase in the "number of *kala azar* deaths registered was very small, 2,244 deaths from that cause having been "registered as against 2,059 in 1895. In the Darrang district as a whole 2,471 *kala azar* deaths were "registered as against 2,477 in 1895. In the Nowgong district 10,588 *kala azar* deaths and 1,905 "deaths from 'other fevers' were registered as against 11,037 and 1753, the respective numbers "registered in 1895. In the district as a whole the registered mortality from *kala azar* was some-"what less, and that from other fevers slightly greater than it was in 1895. As noted in our last "year's report, the recorded mortality from 'other fevers' in this district was so much less than it "was before *kala azar* made its appearance, and it was also so much less than the fever mortality "recorded in neighbouring districts that, in all probability, many deaths which in former years would "have been returned as ordinary fevers were returned in 1896 as *kala azar*.

"Deaths from *kala azar* were very equally distributed throughout the year. The months of "maximum mortality were May, June, and April; and February and January were the months in "which fewest deaths were registered. However, in May, the month of maximum *kala azar* "mortality, only 10·07 per cent. of the *kala azar* deaths occurred, and 7·33 per cent. of the deaths "occurred in February, the month in which fewest *kala azar* deaths were registered. The months of "maximum mortality of 'other fevers' were June, May, and July; and fewest deaths were registered "from the same in April, September, and October. In June, in which the maximum mortality "occurred, 12·44 per cent. of the deaths were registered; and 7·17 per cent. of the deaths were "registered in each of the months of April, September and October, the months of minimum "mortality.

"It is worthy of remark that in all the registration circles of the Darrang district except in the "Mangaldai town circle, the mortality from 'other fevers' was greater than it was in 1895. The "statistics for the year seem to show that *kala azar* has gained a firm footing in all the registration "circles of the Darrang district. Up to last year the only registration areas of the district in which the "disease was prevalent were the Mangaldai town and rural circles."

Kala azar is no new disease. So far back as 1869 the attention of administrative officers had been directed to a peculiar disorder which had decimated and, in some instances, almost totally destroyed the populations of districts in the low, densely-wooded Garo Hills. The Garos themselves gave definite accounts of the invasion of their villages by the disease, and believed it to be infectious; but European medical officers were of opinion that the disease was an intense form of malarial fever, and that there was no evidence whatever to show that it was infectious.

A pamphlet, published by Dr. Kynsey, of Ceylon, which included, among other papers, a monograph by Dr. Lutz on anchylostomiasis, attracted wide notice in India in 1887. Dr. Kynsey proved that anchylostomiasis was the cause of the anæmia prevalent among coolies in Ceylon, and, as anchylostoma were found in the intestines of individuals who had died of anæmia in Assam, Dr. Eteson, in his Sanitary Report for 1887, wrote that there was little doubt that the anæmia and dropsy so prevalent among immigrants in Assam was identical with the so-called *beri-beri* of Ceylon—adopting a misuse of nomenclature which has been fruitful in confusion. At this stage, Dr. Giles was deputed to Assam to enquire into the nature of *kala azar*. Dr. Giles was of opinion that it was anchylostomiasis, complicated no doubt in many instances with the malarial fever prevalent in Assam, but essentially due to the presence in the intestine of anchylostoma.

Soon after the publication of Dr. Giles' report, Dr. Dobson showed that the anchylostomum was a very common parasite in the intestines of the apparently healthy. It had been known before the date of Dr. Dobson's researches that the anchylostomum might be present without causing any appreciable inconvenience to the host, but the establishment of the frequency of the worm's occurrence in India was mainly due to Dr. Dobson. The result of this discovery was to discredit Dr. Giles' hypothesis, and there can be little doubt that there has been a tendency to underestimate the evil which the presence of anchylostoma in the intestine is capable of inducing. In consequence, the pendulum of professional belief swung back to malaria as the cause of *kala azar*, although some medical men, among them Dr. Campbell, who had great experience of the disease, believed that *kala azar* was a paludial fever complicated in the vast majority of cases by the presence of anchylostoma in the intestine.

Owing to the prevalence and spreading of *kala azar*, Dr. Rogers was deputed in 1896 to make another investigation into its nature, and his report was completed early in 1897.

Dr. Rogers gives a useful summary of the growth of opinion regarding the etiology of *kala azar*, and details the clinical and pathological facts observed by him. After stating his own conviction regarding the nature of the disease, he concludes with his recommendations for the prevention of its further spread.

Dr. Rogers describes *kala azar* as having begun in the Garo Hills, and spread thence up the Brahmaputra Valley, along the lines of human communication, desolating villages in its track, but shewing a very distinct tendency to disappear after a variable period from the places that have suffered a visitation.

The symptoms are those of an intense malarial cachexia. Individuals of all ages suffer, but children are especially liable ; the sexes are attacked equally ; no form of occupation ensures immunity, but the very poor are most liable to suffer, and Europeans least so. Dr. Rogers says that seven Europeans have been attacked, and regarding three cases he gives particulars which are unfortunately too meagre to be of much use. Opium-eating seems to afford an almost complete protection.

The seasonal distribution of *kala azar* is almost the same as that of malarial fevers, but more extended—beginning earlier and ending later. It is prone to attack several members of the same family, and in an affected district cases of *kala azar* are more common than are cases of severe malarial cachexia in a malarious district.

Fever is an invariable accompaniment, but it is of no particular type, its only constant characteristic being a tendency to recur again and again until the sufferer dies. One peculiarity of the fever is that the patient is frequently unaware of its existence, even when the thermometer shews that a high degree of fever is present. The disease shews a varying virulency, it is never, Dr. Rogers says, fatal in less than three months, and never lasts for more than three years. Recovery is uncommon, but it is more likely to occur at the end than at the beginning of an outbreak among a community. A characteristic of the disease is a profound disorganization of the digestive functions, and the complete inability to digest vegetable food, which often leads to a craving for an animal diet. The *plasmodium malariæ* was frequently found ; but Dr. Rogers' details on this head are less complete than might have been expected. He found most of the forms "figured by "Italian authors as typical of quotidian fever," but never crescents. A constant sign is enlargement of the spleen, frequently to a very great degree. Although the liver does not appear to be quite so constantly enlarged as the spleen, it is generally enlarged in proportion to the latter organ. Pigmentation of the viscera and of the membranes of the brain appears to be invariable.

All this goes to make up a picture of severe malarial cachexia, and the impression that *kala azar* is a form of malarial disease is deepened by an analysis of twelve cases of which Dr. Rogers gives details. Of these cases only four recovered ; but, in four, death was due to intercurrent diseases. ' It will be noticed by supporters of the theory that *kala azar* is the result of a helminthiasis that in nine of the cases, including all those that were fatal, worms were present in the intestinal tract, and that in many cases, the worms were anchylostomes. At the *post mortem* examination in 25 other cases, anchylostomes were found in 21 ; few in number, it is true, but their small numbers, as well, perhaps, as their absence in four cases, may be accounted for by the administration of thymol to some of the patients during life.

How then may *kala azar* be diagnosed from ordinary severe malarial cachexia ? Dr. Rogers is of opinion that it cannot be diagnosed in the early stages, and that it is only by its peculiar distribution, its tendency to run in families, and the rapid onset of signs of extreme cachexia, that the disease can be distinguished at all. Dr. Rogers, however, repeats the statement that the natives themselves can immediately differentiate the disease from ordinary malarial fever, but, in spite of the importance of this fact, if it is a fact, he does not give any hint as to how the natives arrive at this distinction.

What is *kala azar ?* Dr. Rogers notes that like Dr. Giles he did not succeed in cultivating any micro-organism from the blood, and concludes, perhaps too hastily, that the blood does not contain any cultivable microbe. He vigorously combats Dr. Giles' statement that the disease is anchylostomiasis. In that condition a relative increase of white blood-cells is a prominent feature, whereas in *kala azar*, except when fever is present, the white blood-cells are diminished in proportion to the red cells—the condition of the blood resembling in this respect that described by many authorities as characteristic of malarial cachexia. From the discovery of plasmodia, the constant enlargement of spleen and liver, and the pigmentation of these organs and of the kidneys, Dr. Rogers is convinced that *kala azar* is due to malaria. He believes that it is an intense, contagious form of

malarial disease, and that the organisms generally accepted as the cause of malaria have, on account of continuous favouring circumstances, developed not only great disease-causing power, but the quality of infectiveness either directly or indirectly.

From Salisbury's experiment, which, owing to its quotation by Hirsch,* is well known, it would appear possible that the poison of malaria can be carried from place to place in earth, and Schellong† is of opinion that malaria-germs can be carried into a building and multiply on the walls and on the floors and in clothing ; while there are instances on record where the circumstances were such as to suggest the possibility of direct infection from man to man.‡ In spite of all this, it is the practically universal experience that malarial fevers and cachexia are not infectious, and proofs will have to be indisputable before it can be accepted that *kala azar* is at once due to malaria alone and infectious.

The proof of infectiousness of a chronic disease may obviously be supremely difficult. The facts relied upon by Dr. Rogers are the peculiar distribution of *kala azar* and the histories of its invasion of villages. These narratives are derived from the native headmen, and the validity of the evidence will be contested by opponents of Dr. Rogers' theory on the ground that, according to his own shewing, it is not possible to recognize *kala azar* in its early stages.

Dr. Rogers endeavours to fortify his position by adducing the opinion held by Dr. Jackson regarding the infectiousness of Burdwan fever, and the account commonly given in the text-books of the appearance for the first time in 1866 of malarial fevers in the Mauritius and Réunion. But the Burdwan fever was considered by nearly everyone in a position to form a reliable opinion to be malarial and non-contagious§ ; while the few who thought that it was contagious held, either that it was not primarily malarial at all, or that it was a combination of malarial and typhus fevers‖. The story of the infection of the Mauritius appears to be a medical myth.

An examination of contemporary literature¶ shews that although the inhabitants of the Mauritius had enjoyed comparative freedom from malarial fevers, cases did occur. The British troops quartered in the island were seldom attacked,** and malarial fevers were almost entirely confined to natives of India†† ; still, bilious remittent was endemic, and cases of the same nature as the pernicious intermittent which was the typical fever of the great outbreak were not unknown. The epidemic which occurred in the hot season of 1866–67 was malarial and the fever was readily controlled by quinine. The case-mortality was, therefore, not high among the troops ; and the principal sufferers were natives of India who lived in deplorable conditions of overcrowding and filth, temporarily aggravated by the privations they had to endure consequent on the high prices attending the commercial crisis of the time. The primary cause of the outbreak seems to have been the extension of cane cultivation, which led to deforestation of the island, and so removed the natural protection against excess of rain and drought. The rains of 1865 were so heavy as to cause inundations which left swamps behind them, and the following season was intensely hot and dry. Precisely similar causes were at work in Réunion (Lacaze). Confusion seems to have arisen from the application of the term "Bombay" fever which, according to Small and Power, was merely a name given to malarial fevers because they chiefly occurred among Bombay coolies. But Dr. Barraut showed that the so-called Bombay fever was produced under the same conditions that breed typhus. It was continuous, lasting from 15–20 days ; it was spread by contagion, and just as its prevalence was unaffected by season, so its course was unaffected by quinine. This fever appeared first of all in 1808 among coolies from Bombay, whence it may have been brought by them. It was introduced into Réunion from the Mauritius.

Is *kala azar* due to malaria alone ? If it is, what leads to its unusual distribution ? Is it a disease added to malaria, as scurvy may be added, which, by weakening the affected individual, renders the process of slow degradation due to malarial poisoning a quick one ?

---

Or is it a progressive extension of intense malarial fever due to physical alterations in the soil-and-water-levels in Assam ? These questions remain unanswered.

The number of deaths ascribed to fevers in the North-Western Provinces and Oudh in 1896 was 1,205,964 against 1,093,212 in 1895. The death-rate was 25·71 as opposed to 23·31 in the previous year, and to the mean ratio of 24·19 for the quinquennial period antecedent to the year under review. The heaviest mortalities occurred in December, October, and January, and the lightest in July, June and August. The peculiar rise in March (See the table on page 109) followed by a fall in April, is considered by the Sanitary Commisioner to have been probably due partly to climatic causes and partly to slight scarcity antecedent to the *rabi* crops coming on the market. The mortality in each of the nine months, January to September, was higher than in 1895, but that in each of the last three months was lower. The fall in the last months of 1896 as compared with those of 1895 has already been noticed also in the cases of Bengal and Assam. The mortality, which had been high in October 1896, fell in November, and rose again in December. The fall in November has been attributed to the scantiness of the rains and their premature cessation, the rise in December indirectly to scarcity, which would diminish the chances of recovery of persons attacked by fever or pneumonia. Two of the district death-rates were over 45 per 1,000, those of Pilibhit (48·11) and Naini Tal (45·48), the latter district including the malarious *terai*. Bareilly and Hamirpur had ratios over 40 per 1,000 while five districts had ratios over 35, five over 30, twelve over 25, fifteen over 20, six over 15, and one (Partabgarh) over 5. "Speaking generally," says the Sanitary Commissioner, "it may be said that the incidence of mortality from "fevers fell much more lightly than usual on areas with a normally excessive degree of "humidity of atmosphere and high level of subsoil water, as was to be expected from the "climatic conditions of the year." The rural mortality was 25·52, the rural areas with ratios over 40 being Pilibhit, Naini Tal, Bareilly and Hamirpur. On the other hand, the urban mortality was 28·32, higher than the rural, as it was also in 1893, 1894, and 1895 ; and the highest town ratios were those of Deoband (50·02), Mau Ranipur and the Hardwar Union. Among the large towns with high rates were Ghazipur, Cawnpore, Fyzabad, Ajhudia, Farukhabad, Fatehgarh, Jhansi, Benares and Lucknow.

There was a slight increase in the fever mortality in the Punjab, the number of deaths having risen from 392,118 in 1895 to 393,535, and the ratio per 1,000 of population from 19·08 to 19·15. The ratio for the preceding quinquennium was 23·89. The months of greatest mortality were January, February and October, and those of lowest mortality July, April and August. Like the provinces already treated of, the Punjab had less mortality in each of the last three months of 1896 than in the corresponding months of 1895, but unlike them it had also in 1896 diminished mortality in April, May, June and July. The recorded very high mortality in January is considered by the Sanitary Commissioner to be due to erroneous classification, cases of pneumonia and other chest complaints being, on account of the presence of high body temperature, returned by the ignorant village reporting agents as "fever"; but he does not say why there were more than the usual number of chest complaints in January 1896. From the report of the Inspector-General of Prisons, however, a hint is obtained of the possibility that the high mortality registered in December 1895 and January 1896 may have been connected with the epidemic presence of influenza. Both officers agree, probably with justice, that the general good health of 1895 and 1896 has been due to the scanty rainfall, and consequent prevailing dryness. Three districts had ratios over 25 per 1,000, namely Kangra (29·16), Umballa (25·74), and Rawalpindi (25·20) ; ten districts ratios over 20 per 1,000 ; eleven over 15 ; 6 over 10 ; and one (Montgomery) over 5. The rural death-rate was 19·29, and the rural areas with mortalities between 25 and 30 per 1,000 were Kangra, Umballa and Rawalpindi. The urban death-rate, as usual lower than the rural, was 17·21 ; the highest individual town ratios, just over 23 per 1,000 being those of Rawalpindi, Delhi and Amritsar, and the lowest, between 9 and 10 per 1,000, those of Maghiana, Mooltan and Umballa. The contrast between the town of Umballa and the Umballa rural area is very marked.

In the Central Provinces the deaths from fevers numbered 280,760, or 59,342 more than in 1895 ; and the mortality ratio per 1,000 of population was 29·55 against 23·30 for 1895, 21·23 for the quinquennium, and 20·98 for the decennium. The months of greatest mortality were October, September and August, and those of least mortality June, July, April and May. Every month of the year had more deaths than the corresponding month of 1895. The year 1896 was characterised, according to the Sanitary Commissioner, by irregular

distribution of an average general rainfall, and by the unusually early cessation of a more than average south-west monsoon ; while in his report for 1895 he stated that in that year both the general rainfall and the monsoon rainfall were below the average. The increase of fever in 1896 may therefore have been due to its being a wetter year than 1895. Two districts had ratios over 50 per 1,000, namely, Damoh (58·11), and Saugor (51·04) ; one (Nimar) over 45 ; one (Seoni) over 40 ; four over 35 ; two over 30 ; four over 25 ; three over 20 ; two over 15 ; and one (Sambalpur) over 10. The rural mortality was 30·19, the rural areas with ratios over 50 being Damoh and Saugor, and those with ratios over 40 Nimar and Seoni. The as usual lower urban death-rate was 22·65 ; the towns with ratios above 50 per 1,000 were Rehli and Deori, and those with ratios above 40 Garhakota, Charwa and Burha.

The number of deaths from fevers in Berar was again reduced, though still high, 61,931 being registered against 66,203 in the previous year. The ratio per 1,000 of population was 21·78 against 23·28 in 1895, and against 14·8 for the quinquennium. It has been looked upon as usual for the greatest fever mortality to occur between the beginning of August and the end of October ; but in 1896 the first five months of the year gave by far the greatest number of deaths. Each of the same five months had more deaths, while each of the remaining months of 1896 had fewer deaths than the corresponding months of 1895. This unusual fever mortality during the first five months of the year is believed by the Sanitary Commissioner to be attributable to epidemic influenza. The number of deaths due to malaria in 1896 may therefore very likely have been reduced, and this is all the more probable in view of the fact that the rainfall of the year was short, especially in the third quarter. Two deaths from bubonic plague are included in the figures for October. The highest district ratio was that of Wun (33·8), two districts had ratios over 20 per 1,000, and three over 15. The rural mortality was 21·8, Wun being the only rural area with a ratio over 30. The lower urban death-rate was 21·0, and the towns with ratios over 30 were Yeotmal, Digras, Sirasgaon, Wadegaon and Pusad.

The number of deaths recorded in Madras Presidency as due to fevers was 260,769, or 16,568 less than in the previous year ; while the ratio per 1,000 of population was 7·97 against 8·26 in 1895, and against 7·9 for the quinquennium. The Sanitary Commissioner attributes the decrease to deficient monsoon in the Ceded Districts, where malarial fevers are largely prevalent. In the table given on page 109 it may be seen that the Madras ratio was much lower than that of any other of the British provincial registration areas, and such is usually the case. Deaths were greatest in number in January, December and March, and least in number in June, April and February. Each of the first four months of 1896 had more deaths, and each of the last eight months of 1896 fewer deaths, than the corresponding month of 1895 ; and in this feature Madras is nearly the same as Berar. Three districts had ratios over 15 per 1,000, namely, the Nilgiris (19·5), Kurnool (15·4) and Vizagapatam (15·3) ; three districts ratios over 10, twelve over 5, and four over 2. The rural mortality was 8·0, the Nilgiri rural area having a ratio over 20, and the rural areas of Vizagapatam and Kurnool ratios over 15. The relation between urban and rural fever mortality seems to be abnormal in Madras, as in 1893 and 1894 the former was greater than the latter, and in 1895 and 1896 the two were identical. The towns with ratios of 15 per 1,000 or over were Kampali, Karur, and Palkanda. "In the town of Madras," says the Sanitary Commissioner, "nearer approach to the normal sub-soil water level than has existed since "the exacerbation of malarial fever prevalence attracted attention, namely in 1890, has, in "my opinion, resulted in a decline of the fever rate. On this matter a special report has, "at its request, been submitted to Government." The ratio for Madras was 13·6 against the 14·2 of the previous year. "The town of Karur exhibited a heavy increase of "mortality from fever during the year, namely, 16·5 against 10·6 of 1895. In this "case the sub-soil of the town is saturated with soakage from cesspools, and, as typhoid is "a recognised disease in this town, it need not be assumed that solely malarial fever was "dealt with."

In Coorg there were 3,552 deaths ascribed to fevers, a diminution of 512 ; and the ratio per 1,000 of population was 20·53 against the 23·48 of 1895 and the 19·66 of the quinquennium. The fever mortality ratio was nearly 78 per cent. of the death-rate from all causes. The rural mortality was 21·14, and the urban 14·31. Among rural areas Mercara had the highest ratio, and among towns Fraserpet. June, July, and August were the months that had most deaths, and April, February, and October those that had fewest.

Every month of 1896, except January, March, and December, saw fewer deaths than the corresponding month of 1895.

The total of deaths from fevers registered in Bombay Presidency was 412,229, or 23,381 more than in 1895 ; and in the twelve-year period 1885–96, this number has only twice been exceeded, namely in 1892 and in 1894. The ratio per 1,000 of population was 21·90 against the 20·66 of 1895 and the 21·10 of the quinquennium. Beginning with September the figures include 2,086 deaths from plague. The heaviest mortality characterised the months of January, March, and February, and the lightest the months of June, October, and November. Each of the first seven months of 1896 had more deaths, and each of the last five months fewer deaths, than the corresponding month of 1895 ;* the difference between the two years being least in the months of June, July, and August, and greatest in January, February, and March. The diminution of fever mortality in the latter part of the year may possibly be due to the following of a year of deficient rainfall after another of the same ; but, even if the rise in the beginning of the year was due to the inclusion among fevers of chest complaints and other affections, there is no information as to why those diseases should have been more prevalent. In the case of the Punjab and Berar the cause was shown to have been influenza, but there is no mention of this disease in the Bombay Sanitary Report. Among the troops and prisoners of the Bombay administration cases of influenza were recorded, mostly in January. With regard to the Gujarat Registration District, which, like the Western and the Sind Registration Districts, had higher mortality than in 1895, and which shewed much increase in the first months of the year, little increase in the last three, "the recognised months of malaria," the Deputy Sanitary Commissioner offers the following explanation :—

"During the first nine months of the year small-pox and cholera were prevalent in an epidemic "form throughout the district, and it is possible that many deaths due to one or other of those "diseases were entered as deaths from fever. Moreover, there are many villages in which every "death is returned as due to fever, and consequently in such villages a large proportion of deaths "must be wrongly entered. It is worthy of note that during the last three months of the year, "when malarial fever is most prevalent, the returns for the two years, 1895 and 1896, correspond "fairly accurately ; while the larger divergence occurs in the latter part of the cold weather, when "deaths from chest affections are most liable to occur, and in the hot weather and first months of the "monsoon, when epidemic diseases are most prevalent."

The districts with the highest ratios, over 30 per 1,000, were Broach (33·23), Nasik (30·33), and Kaira (30·20) ; and five districts had ratios over 25, nine over 20, four over 15, and three over 10. The rural mortality was 22·50, and the rural areas with ratios over 30 per 1,000 were Broach, Nasik, Kaira. The urban mortality, 17·59, was, as usual, lower than the rural ; the towns with ratios over 30 being Barsi, Nasik, Nadiad, Dohad, Umarkot, and Shikarpur.

The number of deaths registered in Lower Burma under the heading of fevers in 1896 was 51,521 as compared with 48,049 in the previous year ; and the death-rate was 11·41 against the 10·64 of 1895 and the 10·02 of the quinquennium. The months of greatest mortality were December, August, and July, and those of least mortality March, May, and April, and in each month of 1896 there were more deaths than in the corresponding month of 1895. The mortality of 1896 from fevers is the highest recorded in the 25 years, 1872–96. No explanation of the increase is forthcoming. The highest district death-rate was that of Akyab (20·51), and the lowest that of Hanthawaddy (5·01). One district had a ratio over 20 per 1,000, two districts ratios over 15, six over 10, and nine over 5. The rural mortality was 11·87, and the urban 8·39. No rural area had a higher ratio than 21·55, and none a lower than 5·01, the areas with the highest ratios being Akyab, Tharrawaddy, Sandoway, and Prome, those with the lowest Hanthawaddy and Amherst. The maximum for towns was 21·96, and the minimum 1·47. Among the towns with high ratios were Kawkareik, Pegu, Pantanaw, Sandoway, and Ramree, and among those with low ratios Danubyu, Yandoon, Zalun, Ngathainggyaug, Thayetmyo, and Shwedaung.

Dysentery and diarrhœa.

The number of deaths attributed to dysentery and diarrhœa throughout the registration areas of India during 1896 was 240,189, a reduction of 2,343 ; and the ratio per 1,000 of population was 1·10 against 1·11 in the previous year, the number under registration having somewhat diminished in 1896. The months of greatest mortality were August,

* Each of the first nine months of 1896 had more deaths, and each of the last three months fewer than the corresponding monthly mean of the decennium 1886–95.

September, and July, and those of least mortality February, March, and January. Each of the six months February–July had more deaths, and each of the others fewer deaths, than the corresponding month of 1895.

The highest provincial death-rate was that of Berar, where also the highest district death-rate was recorded ; and the lowest that of Bengal. Leaving out Coorg, the lowest maximum district death-rate occurred in the Punjab. The Central Provinces shewed the greatest increase of ratio, and Berar the greatest decrease. Assam, the Central Provinces, Madras, and Bombay registered increased mortality, the difference in the case of Madras being very small ; while the other eight provincial areas rejoiced in lowered ratios. The only province in which the rural mortality exceeded the urban was Berar ; but no explanation of this exceptional relation is offered.

The following statement illustrates not only what has just been written, but also the succeeding paragraphs upon bowel complaints in the different provinces :—

Statement shewing the Deaths from Dysentery and Diarrhœa registered in the different Provinces by Months during the year 1896.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.		RATIO OF DEATHS PER 1,000 OF POPULATION.	
													1896	1895.	1896.	1895.

The number of deaths registered in Bengal under dysentery and diarrhœa in 1896 was 47,935, or 1,936 less than in the preceding year ; and the ratio per 1,000 of population was 0·67 against the 0·70 of 1895 and the 0·69 of the quinquennium. The months of greatest mortality were June, August, and March, and those of least mortality November, October, and December. Each of the seven months, February to August 1896, had more deaths, while January and each of the last four months of 1896 had fewer than the corresponding month of 1895. The maximum district ratio was 6·69 in Darjeeling, and the minimum 0·02 in Rajshahi. One district had a ratio over 5 per 1,000, two ratios over 4, one a ratio over 3, two ratios over 2, six over 1, six over 0·5, twenty-five over 0·05, and three under 0·05. The districts of Darjeeling, Howrah, Calcutta, Balasore, Puri, Hooghly, and Cuttack, though they do not stand every year exactly in the order now given, always have the highest mortality ratios. The Sanitary Commissioner, however, says :—

" The figures cannot be trusted. It is a matter of common knowledge that dysentery and diarrhœa " are prevalent diseases all over Bengal—diseases to which many persons succumb—yet the rates of " mortality returned would lead one to suppose that, except in the half-dozen districts mentioned, " dysentery and diarrhœa prevail to a slight extent only. There is reason to believe that a large " number of deaths from this cause are returned as fever by ignorant *chaukidars*, who are the recorders " of vital statistics. In the districts at the top of the list I believe it has become the custom to return " a comparatively high death-rate from this cause, which is the only explanation I can give ; for there " is no reason why dysentery and diarrhœa should be more prevalent in Howrah, Calcutta, Balasore, " Puri, Hooghly, and Cuttack than in other parts of the province."

The urban mortality (3·22) was, as in past years, enormously greater than the rural (0·54). The rural areas with the highest ratios were Darjeeling and Howrah, and the towns Bhadreswar (12·76), Serampore, Chaibassa, Howrah, Midnapore, Kurseong, and Hooghly with Chinsurah. The first, second, and last of these towns had also very high ratios in the preceding year.

In the port of Calcutta there were 61 admissions but no deaths among European seamen ; while in the native floating population there were 9 deaths, all out of hospital, or 0·35 per 1,000 of strength.

There were 16,004 deaths registered as due to dysentery and diarrhœa in Assam in 1896, an increase of 481 ; and the death-rate was 3·19 per 1,000 against 3·09, the death-rate of the previous year, and against 2·94, the quinquennial mean death-rate. The months of greatest mortality were November, October, and June, and those of least mortality February, April, and March. April, September, November, and December had fewer deaths than the corresponding months of 1895 ; the other months, more deaths. In accordance with past experience, the district with the highest death-rate was Lakhimpur (7·16), and that with the lowest Goalpara (0·63). One district had a ratio over 7 per 1,000, two ratios over 4, three ratios over 3, one a ratio over 2, one a ratio over 1, and one a ratio over 0·5. The rural mortality was 3·12 and the urban 6·25. Lakhimpur and Cachar were the rural areas with the highest ratios, and Mangaldai and Golaghat the towns.

The total number of deaths ascribed to dysentery and diarrhœa in the North-Western Provinces and Oudh in 1896 was 40,858, a reduction of 1,920 ; and the death-rate was 0·87 against the 0·91 of 1895 and the 1·00 of the quinquennium. The months of greatest mortality were September, August, and October, and those of least mortality February, March, and January. The six months, January–June, had fewer deaths, the four months, July–October more deaths, November fewer deaths, and December more deaths than the corresponding months of 1895. The provincial Sanitary Commissioner considers the rise in December to have been due partly to climatic causes and partly to scarcity. The hill tracts, as usual, showed high rates. The highest district ratio (8·9) was that of Garhwal, and the lowest (0·05) that of Ballia and of Jaunpur. One district had a ratio over 8 per 1,000, two over 5, one over 4, three over 2, nine over 1, five over 0·5, and twenty-seven of 0·05 or over. The rural mortality was 0·76, the urban 2·40 ; the rural areas with the highest ratios being Garhwal and Jhansi, the towns Hardoi (40·89), Kashipur (16·37), Lalitpur and Rath. At Hardoi a heavy mortality occurred among the famine-stricken inhabitants of the poor-house ; while Kashipur, a town in the Naini Tal district, is said to be noted for the frequent occurrence of dysentery and diarrhœa.

There were 13,886 deaths attributed to dysentery and diarrhœa in the Punjab, a reduction of 1,762 ; and the ratio per 1,000 of the population was 0·68 against 0·76 in the previous year, and 0·81, the quinquennial mean. The heaviest mortalities occurred in the months of September, October, and August, and the lightest in February, March, and June. February, March, August, and September had more deaths, all the other months fewer deaths, than the corresponding months of 1895. "The year taken as a "whole," says the provincial Sanitary Commissioner, "has shown a death-rate considerably "below the mean for the ten preceding years, a fact which I am inclined to ascribe to the "dry season we experienced in 1896, especially as the worst months in 1895 also shew a "mortality considerably below the mean, that year being also an unusually dry one." The highest district ratio was that of Simla (3·26) and the lowest that of Hazara (0·11). One district had a ratio over 3, five a ratio of 1 or over 1, thirteen ratios over 0·5, and twelve ratios over 0·05. It is said to be usual for the death-rates of the districts of Simla, Gurgaon, Kangra, Delhi, Gurdaspur, Umballa, Karnal, and Hissar to be comparatively high. The rural mortality was 0·58, the urban 2·0 ; the rural area with the highest ratio being Simla, and the towns with the highest ratios Pind Dadan Khan, Bhiwani, Kaithal, and Rewari.

The number of deaths registered under dysentery and diarrhœa in the Central Provinces was 29,882, an increase of 9,566 ; and the death-rate per 1,000 of population was 3·15 against the 2·14 of 1895 and the 1·84 of the quinquennium. The months of greatest mortality were August, September, and October, and those of least mortality January, March, and February. Each month of the year 1896 saw the occurrence of more deaths than the corresponding month of 1895. The monsoon rainfall was irregularly distributed, and ceased very early ; the crops were below the average ; there was widespread distress and scarcity ; and the increase of bowel complaints was due to insufficiency of the usual food, and to the consequent ingestion of unsuitable food-stuffs. The highest district ratios were those of Jubbulpore (9·79), Damoh, Murwara, and Mandla (7·68), and the lowest district ratio that of Bhandara (0·25). Three districts had ratios over 9 per 1,000, one over 7,

two over 4, three over 3, two over 2, eight over 1, and one over 0·05. The rural death-rate was 2·75 against 2·04 in the previous year; the rural areas with the highest ratios being Jubbulpore, Mandla, Damoh, and Murwara. The urban mortality was 7·44 against 3·19 in 1895; and with regard to individual towns, Damoh had a ratio over 70 per 1,000, Murwara over 60, Khurai over 40, Sehora over 30, Narsinghpur, Lakhnadan, Hatta, and Jubbulpore over 20; Gadarwara, Burha, Mandla, and Mungeli over 10.

The total number of deaths registered as due to dysentery and diarrhœa in Berar in 1896 was 17,722, a reduction of 6,730; and the death-rate was 6·23 per 1,000, as compared with 8·60 in the previous year, and with 6·1, the mean death-rate of the previous five years. The heaviest mortalities occurred in the months of August, April, and September, and the lightest in the months of December, June, and November. Each of the first four months of 1896 had more, and each of the other months fewer, deaths than the corresponding month of 1895. The highest district death-rate was that of Ellichpur (10·3), and the lowest that of Wun (2·7); and this relation is a usual one. The other districts had ratios of 8, of over 6, and of over 5. The rural mortality was 6·5, and the urban 4·5; and in at least the three preceding years also the rural ratio was higher than the urban. No explanation is given as to why Berar differs in this point from other provinces. Among rural areas Ellichpur had the highest ratio, and among towns the highest ratios were those of Nandura, Karajgaon, Bulgaon, and Ner Pinglai.

The total number of deaths registered under dysentery and diarrhœa in Madras Presidency in 1896 was 24,802, an increase of 865; and the death-rate was 0·76, or 0·05 more than in 1895, and 0·04 less than the mean of the five years preceding. The months of greatest mortality were December, September, and August, and those of least mortality April, March, and February. The first six months of the year and August had each fewer deaths, the other months each more deaths, than the corresponding month of 1895. The increase in the second half of the year, and especially in December, is probably connected with the prevalence of cholera. The highest district ratio was that of Madras (5·3), and the lowest that of Kurnool (0·2). One district had a ratio over 5, one over 2, three over 1, eleven of or over 0·5, and six over 0·05. The rural mortality was 0·5, and the urban 3·2. With regard to Chingleput, which had the highest ratio among rural areas, the Sanitary Commissioner says:—

"This district is notorious for bowel affections. The increase may be due to a better rainfall in "certain parts of the district than it has had for some years past bringing about access of water to tanks "from more than usually distant parts, and with it filth that would have been out of range of influ- "ence in ordinary years, or to fluctuation of the sub-soil water beyond normal limits. It is probable "that much of the so-called dysentery and diarrhœa of South Canara and Malabar is due to catarrhal "inflammation of the intestines following exposure to wet, which must form a prominent feature of "the every-day life of the labourer in these districts."

Over 7 per 1,000 was the ratio of the town of Coonoor, and over 6 per 1,000 the ratios of Tanjore, Vizagapatam, Calicut, and Tuticorin.

During 1896 the number of deaths under dysentery and diarrhœa in Coorg fell only from 367 to 323, thus remaining much higher than in 1894 and 1893. The ratio of 1896 was 1·87, that of 1895 2·12, and that of the quinquennium 1·38. In August and July the deaths were most, and in February and March least, numerous. January, April, and August were the only months of 1896 that had more deaths than the corresponding months of 1895, and in April the difference was very slight. The rural mortality was 1·42, and the urban 6·38. Among rural areas Kiggatnad had the highest ratio (2·33), and among towns Virajendrapet (17·32).

During 1896 the number of deaths from dysentery and diarrhœa in Bombay Presidency was 36,046, an increase of 698; and the ratio per 1,000 of population was 1·92 against the 1·88 of 1895 and the 1·87 of the quinquennium. The months of greatest mortality were August and July, and the months of least mortality March and February. Each of the first eight months of 1896 had more, and each of the last four months fewer, deaths than the corresponding month of 1895. The central registration district only had a decrease of ratio, the other four shewing an increase. The highest district death-rate was that of Nasik (4·73), and the lowest that of Upper Sind Frontier (0·05). One district had a ratio over four per 1,000, three districts ratios over 3, six over 2, four over 1, and ten of or over 0·05. The rural mortality was 1·86, the rural areas with the highest ratios being Nasik and Belgaum, and those with the lowest Panch Mahals and Hyderabad. Greater was the urban death-rate, namely, 2·33; and the towns with the highest ratios were Nandurbar, Nasik, Chopda, and Ahmednagar.

In Lower Burma the number of deaths registered from dysentery and diarrhœa was 7,777, or 1,017 less than the number of the previous year, which was, chiefly on account of improved registration, the highest number ever recorded. The ratio per thousand of population was 1·72 for 1896, 1·95 for 1895, and 1·43 for the quinquennium. Deaths were most numerous in July, August and June, and least so in April, March and February. May, September, October, and November, had each more deaths, and the other months each fewer deaths, than the corresponding month of 1895; but the difference in May and June was very small. The highest district ratio was that of Tavoy (4·84), and the lowest that of Prome and of Henzada (0·63). One district had a ratio over 4 per 1,000, three districts ratios over 3, two over 2, nine over 1, and three over 0·5. The rural mortality was 1·62, and the urban 2·38. The rural areas with the highest death-rates were Tavoy, Bassein, and Myaungmya. Some of the towns had high ratios, such as Thaton, Maubin, Ramree, Bassein, and Myanaung; others, such as Kyangin, Zalun, Thayetmyo, etc., had very low mortalities; while two recorded no deaths at all. With regard to these differences the Sanitary Commissioner remarks :—

"Some of these towns get their water-supply from rivers; some partly from rivers, partly from "wells; and some have to rely on wells entirely. No relation between these various sources of supply "and the incidence of bowel complaints is discernible, nor can any be traced in the sanitary defects "or meteorology."

Injuries. The deaths recorded under "Injuries" during 1896 numbered 92,531, or 2,029 less than in the preceding year; but as the population under registration also fell, the ratio 10·43 per 1,000 remained unchanged. The whole reduction took place in five provinces, there having been more or less increase in seven. The ratio of mortality ranged from 0·67 in the Central Provinces to 0·23 in Lower Burma. As in the previous year, the months that saw most deaths from injury were July and August.

Statement shewing details of deaths from Injuries registered in the different Provinces during the year 1896.

Province.	Population under registration.	Details of Deaths from Injuries.				Total.
		Suicide.	Wounding.	Accident.	Snake-bite or killed by wild beasts.	
Bengal	71,070,233	3,456	1,628	12,729	10,609	28,422
Assam	5,021,084	107	133	1,097	255	1,592
N.W. Provinces and Oudh...	46,904,791	3,480	1,760	16,253	6,960	28,453
Punjab	20,553,982	376	680	4,725	1,312	7,093
Central Provinces	9,501,401	1,161	825	3,022	1,383	6,391
Berar...	2,843,222	163	56	536	168	923
Lower Burma	4,514,773	70	188	265	505	1,028
Madras Presidency... ...	32,721,267	1,867	6,612		2,343	10,822
Bombay „	18,820,346	684	633	3,538	1,383	6,238
Ajmere-Merwara	542,358	9	13	203	55	280
Coorg...	173,055	7	7	39	3	56
Mysore	4,843,523	104	927		202	1,233
Total	217,510,035	11,484	55,869		25,178	92,531

All other causes. The number of deaths recorded under "All Other Causes" was 1,358,260 against 1,282,141; and all the provincial registration areas, except Berar, Coorg, and Mysore, shared in the increase. As in the preceding year, the greatest monthly record under this heading was in December.

Vaccination.

The total number of vaccinations performed in 1896–97 by all agencies among the civil population throughout British India was 8,019,856, as compared with 7,912,086 in 1895–96. Of the total, 7,385,791, were primary operations, of which 6,936,842 succeeded, and 634,045 were re-vaccinations, of which 388,251 proved successful. Notwithstanding the general increase, there was a falling off in some provinces, either in the number of primary operations, or in the number of re-vaccinations, or in the numbers of both, the total diminution being most marked in the Punjab and the Central Provinces.

As usual, the average number of vaccinations performed by vaccinators was highest in the Punjab and lowest in Bengal. In the vaccinations performed by the special establishments, the percentage of success in primary cases varied between 92·01 in Lower Burma, and 98·62 in Bengal, and in re-vaccinations between 20·5 in Berar, and 94·25 in Assam. In the operations performed by the dispensary establishments the ratio of success in primary cases was highest, 96·04 per cent. in Bengal, and lowest, 52·07 in Coorg ; and in re-vaccinations it ranged from 19·02 per cent. in the North-Western Provinces and Oudh, to 76·35 in Assam.

The state of infant vaccination is still backward in Bengal, Assam, Madras, Coorg and Upper Burma, but the number of infants protected were, in every province except Assam, the Punjab and the Central Provinces, greater than in 1895–96. The total number of children under one year of age, who were successfully vaccinated was 2,903,167, and of those between one year and six years of age 3,237,849, against 2,751,764 and 3,372,925, respectively, in the preceding year. The proportion of persons successfully vaccinated per thousand of population was everywhere greater than in 1895-96, except in the Punjab, the Central Provinces, Bombay, and Coorg.

The following comparative statement shews in outline the work of the Vaccination Departments during 1895-96 and 1896-97 :—

Comparative statement of vaccination in the different Provinces of India, excluding Ajmere-Merwara, in 1895-96 *and* 1896-97, *together with the death-rates from Small-pox during* 1895 *and* 1896.

Province.		Population.	Number of vaccinations performed.			Percentage of successful cases.		Persons successfully vaccinated per 1,000 of population.	Ratio of deaths from small-pox per 1,000 of population during the calendar years 1895 and 1896.	Average number of vaccinators employed in Department.*	Average number of operations per vaccinator.*
			Primary.	Re-vaccinations.	Total.	Primary.	Re-vaccinations.				
Bengal	1895-96	70,761,383	2,227,932	49,149	2,277,081	97·84	41·85	31·09	0·18	3,380	639
	1896-97	71,053,516	2,223,128	70,527	2,293,655	97·92	52·60	31·16	0·18	3,478	622

* Refers to special vaccination establishments only.
† Calculated on figures taken from Sanitary Reports excluding Upper Burma.

Animal vaccination.—In the paragraphs dealing with the various provinces details will be found regarding the different kinds of vaccine material in use. It will be observed that bovine vaccination is making steady progress. The calf lymph is used either direct from the vaccinifer or kept without admixture for a very short time before use. For preserving stocks and for the distribution of vaccine, the lymph is made into pastes with glycerine, or lanoline,

or vaseline. The vaseline paste, to which special attention was directed in last year's report, was introduced into the Punjab by Drs. Roe and Bamber, but its use has not proved quite so successful as was expected. It may be noted that a vaseline preparation was tried and discarded by Dr. Little in Berar so far back as 1889.

In connection with the preservation of calf lymph, reference must be made to a very important recently published article* by Drs. S. Monckton Copeman and F. R. Blaxall.

In 1891 Dr. Copéman presented a paper to the International Congress of Hygiene, in which he called attention to the purification from extraneous organisms that vaccine lymph underwent after storage for several weeks with a mixture of chemically pure glycerine and distilled water. Since then several observers have confirmed this result. In accordance with a suggestion contained in Section 448 of the Report by the Royal Commission on Vaccination, Dr. Copeman made arrangements with Dr. Blaxall to carry out a series of experiments to elucidate more fully the comparative merits of the glycerine method and other methods for the purification and preservation of animal lymph. Dr. Blaxall investigated the action on vaccine material of glycerine, lanoline, and vaseline, and found that, while extraneous microbes were killed after storage of the lymph with glycerine, their numbers were largely increased after storage with lanoline and vaseline. He found further that lymph taken from calves that had been vaccinated with vaccine rendered free from extraneous microbes by glycerine storage, was often remarkably free from extraneous micro-organisms. In his experiments Dr. Blaxall made use of Price's "Pure Glycerine" of a specific gravity of 1·260; it was thoroughly mixed with sterilized distilled water to 50 per cent. by weight, and the mixture was sterilized. Four parts by weight of the sterilized mixture were added to one part of the vaccine material and stored for a month, when it was found to be free from extraneous organisms.

In commenting on the experiments, Dr. Copeman lays stress on certain precautions that should be taken in the preparation of the glycerine emulsion. Chemically pure glycerine should be used and should be mixed with distilled water. The mixture should be sterilized before being added to the vaccine material, and it should be added in a definite proportion. Dr. Blaxall used 4 to 1, but a much higher dilution, 15, and even 20, to 1 by weight, was used successfully by the German Commission of 1896. Lastly, the emulsion should be protected from light and air.†

In India we have to contend not only with adventitious organisms, but frequently with the effect of great heat in destroying the specific action of the vaccine. While some prefer glycerine-vaccine to lanoline-lymph-paste, complaints of ill effects produced by the latter have not been numerous, and it would be possible to make too much of the theoretical advantage enjoyed by the glycerine preparation. Still the advantage is undoubted, and it seems very necessary that experiments should be undertaken to ascertain the effects of diluted glycerine on the bacterial flora of Indian lymph, as well as to obtain more precise data than have been recorded hitherto regarding (*a*) the "age" at which vesicles yield the most effective lymph in different conditions; (*b*) the proportions of glycerine and water and lymph which give the best result; and (*c*) the effect of heat on the keeping qualities of the emulsion.

During the year 1896–97, the inspecting staff in Bengal consisted of the Sanitary Commissioner and his three Deputies, 48 Civil Surgeons, 207 Native Inspectors and 13 Head Vaccinators; and the operating staff of 140 vaccinators paid by Government, 60 paid by District Boards, 253 in the employment of municipalities or attached to dispensaries, and 3,278 men who receive no salary but are licensed by Government to vaccinate for fees. As compared with the previous year there was a decrease of 4 Inspectors and of 40 salaried vaccinators, and an increase of 44 licensed vaccinators and 76 apprentices.

---

* Report of the Medical Officer of the Local Government Board for the Year 1895–96, Appendix C.

† Since this was in type, the report of the Medical Officer of the Local Government Board for 1896–97 has been received. It contains (No. 6) a report by Drs. Thorne Thorne and Monckton Copeman on glycerinated calf lymph. The reporters visited Paris, Brussels, Berlin, Dresden, Cologne and Geneva. In Paris alone did they find vaccination carried on under official sanction with crude calf lymph, and even there the process was limited to vaccination direct from calf-to-arm—and this only to convince certain classes that the lymph used was derived from the calf; all lymph stored for distribution being glycerinated. In Germany they were informed that the system of vaccinating direct from the calf had come to be abandoned as completely as from arm-to-arm; the use of glycerinated calf lymph having become general throughout the Empire.

In the French army from the 1st November 1897, the exclusive use of animal lymph has been prescribed, and it is to be supplied from five depôts in Paris, Lyons, Chalons, Bordeaux and Algiers. It is mixed with glycerine. *Hygienische Rundschau* No. 1, 1898, p. 48.

The total number of operations performed by all agencies throughout the province was 2,293,655—an increase of 16,574, which is the more satisfactory when the difficulties which the department had to encounter during the year are considered. There was an increase in the work done in 26 districts; most noticeable in Backergunge, Cuttack, Chittagong, Shahabad and Bankura; and a decrease in 23. The greatest falling off in the number of operations was in Saran, where high prices of food-grains left the people no money to pay the licensed vaccinators. The same causes were at work in most of the districts, and in some of them the public health was very bad. In Faridpur the decrease as compared with 1895–96 is attributable to the exceptional amount of work done in that year when vaccination was accepted by the Ferazi Mahomedans; and the apparent falling off in Mymensingh was also due to an unusual number of operations having been performed in the previous year when small-pox was epidemic in the district.

The ratio of success in primary operations was 98·50, or 0·11 per cent. higher than in 1895–96. The high percentage recorded unfortunately does not represent the facts and is due to the dishonest practice of the vaccinators, who, in many cases, do not enter the names of the children they have operated upon until the vaccination is successful, and frequently reckon as successful, partial, and even absolute, failures. The number of re-vaccinations was 70,527, of which 60·23 per cent. succeeded, the high ratio being accounted for by the fact that in many cases the operation was repeated until it was successful. It is satisfactory to notice that, in spite of the scarcity, the improvement in the protection of infants was more than maintained. Estimating the number of infants available at 40 per thousand of the census population, 17·6 per cent. were successfully vaccinated in 1896–97 against 14·7 in 1895–96, and a mean of 12·8 in the preceding three years.

Of the various agencies employed, only the vaccinators paid by District Boards and Municipalities did more work than in the previous year, the average number of operations performed by each man having been 979 against 881. The licensed vaccinators performed on an average only 621 operations, or 20 less than in 1895–96, but they were, as already explained, specially affected by the poverty of the people. The vaccinators paid by Government vaccinated on an average only 441 against 481 in the previous year, the falling off being due to disappointment felt by them when they learned, towards the end of the year, that the districts in which they worked were to be thrown open to licensed men. The Deputy Sanitary Commissioners verified only 0·45 per cent. of the total operations, because, during the working season, from October until the end of March, they were employed on plague duty. All other inspecting officers verified larger numbers than in the preceding year; Civil Surgeons 9·56 per cent. against 8·80; District Inspectors 38·47 per cent., against 32·77, and Sub-Inspectors 65·34 per cent. against 62·52. The Civil Surgeon of Dacca verified 13,626 cases, the Civil Surgeon of Darbangha (Dr. E. H. Brown) 13,581, and the Civil Surgeon of Backergunge (Dr. K. P. Gupta) 13,288; four Civil Surgeons* inspected more than 10,000 operations, and thirteen others from 5,000 to 10,000. The percentages of operations inspected and found successful were, by Deputy Sanitary Commissioners, 84·71, by Civil Surgeons, 95·56, by District Inspectors, 96·93, and by Sub-Inspectors, 97·14.

Vaccination was carried on as usual with fresh calf lymph, calf lymph mixed with lanoline, and humanized lymph. There was a considerable increase in the amount of lanoline lymph paste manufactured in Calcutta and a slight decrease owing to difficulty in getting calves in Darjeeling. The use of calf lymph, fresh and prepared, is extending rapidly—so rapidly that Dr. Dyson believes that its use will soon supersede arm-to-arm vaccination in Bengal. There was also a considerable demand for lanoline lymph from Nepal, and 1,845 grains were supplied.

Excluding the staffs of dispensaries and the employés of tea-garden proprietors, there were employed on the work of vaccination in Assam, 18 Native Inspectors, 175 vaccinators paid by Government, 28 licensed men and 6 apprentices. The total number of operations performed rose from 233,812 in 1895–96, to 250,350, and the average number performed by each vaccinator from 1,025 to 1,103. Of the total 243,307 were primary vaccinations and 7,043 were re-vaccinations, the percentages of success claimed being 97·58 and 94·25, respectively, as compared with 97·74 and 87·98 in the previous year. The ratio of success in primary operations, although slightly lower than in 1895–96, is still very high. It has been ascertained by special enquiries made by Civil

*Including those mentioned.

Surgeons that vaccinators are not in the habit of excluding unsuccessful cases from their returns, and the Sanitary Commissioner records it as his opinion that the high rate of success is due to the excellent quality of the lymph supplied from the depôt at Shillong. The very high and increasing ratio of success in re-vaccinations, regarding which no attempt at explanation is made, would itself cast doubt upon the accuracy of the reported results even if an examination of the district returns revealed no suspicious figures. For instance, in the district of Nowgong, there were 12,970 primary operations performed by the special staff, and every single operation is stated to have been successful! Even if it is admitted that real insusceptibility to vaccination does not exist—and the vaccinators of the Local Government Board did not meet with a single instance during fifteen years in upwards of 95,000 consecutive primary vaccinations—still, in the absence of the highest skill, "insusceptibility" does occur. In England in 1893, the returns from the provinces showed 3·4 per thousand of the children born to be insusceptible, and the figure in the metropolitan returns was 5·3. Moreover, in Nowgong itself, of 237 primary operations performed by the dispensary staff, only 91·56 per cent. succeeded. There was again a marked diminution in the number of operations performed by Civil Surgeons and dispensary staffs; the numbers have fallen from 12,302 in 1894–95 to 10,456 in 1895–96 and to 8,072 in 1896–97. Of these, 7,590 were primary operations, and 482 re-vaccinations, with ratios of success of 94·26 and 76·35 per cent. respectively, as compared with 95·08 and 82·26 in 1895–96. By the tea-garden agencies 16,274 operations, all of which were primary, were performed, and 82·79 per cent. proved successful. In certain gardens at Mazdu, Ghilacherra and Jagcherra in the Sylhet District, the results were most unsatisfactory, for out of 2,398 vaccinations performed during the year only 103 succeeded.

The number of infants protected was 20·4 per cent. of the total number of births, estimated at 40 per 1,000 of the census population, against 20·9 in 1895–96, and 17·6 the mean of the previous three years.

Of the total number of operations performed, the results of 7·98 per cent. were inspected by Civil Surgeons who found 98·38 of the cases successful; 60·90 per cent. were verified by Native Inspectors and 97·68 found successful. In ten towns, with an aggregate population of 66,313, where vaccination is compulsory under the law, 4,222 operations were performed, of which 3,685 succeeded; 618 notices were issued under the Act, but not a single person was prosecuted.

Inoculation is still practised in Sylhet, Silchar and Lakhimpur and in the Garo Hills. The Civil Surgeon of Sylhet reported "that there was reason to believe that an outbreak "of small-pox in Burunga village in the North Sylhet sub-division was due to "inoculation."

The working of the Bovine vaccine depôt at Shillong was satisfactory, and the lymph supplied from it during the year was reported by all Civil Surgeons to be excellent. Certain experiments were made by six Civil Surgeons with calf lymph mixed with glycerine and with lanoline lymph paste. The results obtained with the two preparations were practically the same. The Sanitary Commissioner, however, prefers the glycerinated lymph as it keeps better; not on account of any quality inherent in the preparation, but because it is distributed and stored in hermetically sealed tubes.

In the North-Western Provinces and Oudh the supervising staff consisted of two Deputy Sanitary Commissioners, 48 Civil Surgeons and 49 Assistant Superintendents, and the average number of operators was 878. In spite of scarcity, of the cessation of the operating season fifteen days earlier than in past years, and of the employment of a very considerable number of vaccinators at relief works in connection with cholera, and on plague duty, the total number of operations rose from 1,497,899 in 1895–96, to 1,527,308. Of these, 1,442,743 were primary operations, and 94·65 per cent. succeeded; of the 84,565 re-vaccinations, 68·77 succeeded. The number of vaccinations per man fell from 1,754 to 1,739. In addition to the work of the regular staff, 988 primary operations and 185 re-vaccinations, of which 92·82 per cent. of the former and 19·02 per cent. of the latter proved successful, were performed at dispensaries. The number of infants protected during the year was again higher than in the preceding year, and rose from 570,227 in 1895-96, to 578,390. The interest taken in vaccination in the different municipalities appears to vary considerably, but in many instances the Civil Surgeons, who are Superintendents of Vaccination in the municipalities, were occupied with other important work.

The number of inspections made by supervising officers was somewhat less than in the preceding year; the percentage of the total verified by Deputy Sanitary Commissioners

and Civil Surgeons was 9·05, against 9·6 in 1895–96; and by Assistant Superintendents 27·77 per cent. as compared with 29·83. The percentage found by the former to be successful was 94·01, and by the latter 93·17.

During the year, the question of the entertainment of estate vaccinators was taken up. It was arranged that each estate large enough to afford employment for a vaccinator should pay for one; smaller estates, in a position afford it, to join with one or more others to pay for a vaccinator or to give contributions in cash to the cost of district vaccinators.

The supply of lymph from the hills was sufficient and satisfactory.

In the Punjab the supervising staff comprised one Deputy Sanitary Commissioner, six Divisional Inspectors and 34 Native Supervisors. Besides these, Civil Surgeons exercised general supervision in their districts, and carried on inspections during their tours. The average number of vaccinators, including the special staff and men entertained by Cantonment Committees, was 303, or three more than in 1895–96; but, while the number of operators was slightly increased, the number of operations performed was much less than in the previous year—the falling off amounting to 20,666 primary operations, and 96 re-vaccinations. The circumstances brought forward by the Sanitary Commissioner as leading to the diminution of work done are not considered by the Local Government to be the real causes. Stricter supervision on the part of inspecting officers may, however, have something to do with it, for the decrease in work is due entirely to a diminished outturn by the district staff. They performed 596,686 primary operations, 28,210 less than in 1895–96, and 188,777 re-vaccinations, or 16,055 fewer than in the previous year. Meanwhile the special staff performed 67,780 primary operations, or 6,072 more than in the preceding year, while the number of re-vaccinations performed by them was 34,113, or almost double the figure of 1895–96. The dispensary establishments vaccinated 3,737 persons primarily, and re-vaccinated 2,227, against 2,282 and 987, respectively, in the preceding year. The cantonment vaccinators performed 4,875 primary operations and 4,218 re-vaccinations against 4,858 and 6,015, respectively. The percentage of success in primary operations attained by the district staff was 93·97, against 93·36 in the previous year; by the special staff 86·93, against 90·29; by dispensary establishments 89·11 per cent., against 93·38; and by cantonment vaccinators 91·92, against 94·77. The percentage of success in re-vaccinations attended by the district staff was 59·19, and by the special staff 61·84.

Among Native States, Patiala headed the list with 92,509 operations, but here again there was a falling off of 6,336 in the total performed, although the ratios of success, 95·46 in primary cases and 47·63 in re-vaccinations, were considerably higher than in the previous year.

The number of infants protected was 58·5 per cent. of the estimated number of births, against 58·8 per cent. in 1895–96. Civil Surgeons inspected 9·86 of the primary operations and 4·98 per cent. of the re-vaccinations; native Supervisors 57·43 per cent. of the primary operations and 31·01 per cent. of the re-vaccinations; Divisional Inspectors 15·56 and 9·31 per cent., respectively. The percentages of success found by the various inspecting officers were in almost all instances, except in the comparatively small number of re-vaccinations verified by the Divisional Inspectors, much higher than those claimed by the vaccinators.

The vast majority of the operations were performed with calf lymph without admixture, and the ratio of success attained in primary operations was very high,—99·1 per cent. *Humanized lymph* was used in 42,825 primary operations, and 98·8 were successful. *Vaseline lymph* was used in 70,199 cases and only 92·6 succeeded. But although vaseline lymph was less efficacious in primary cases, it was most efficient in the large number of 22,009 re-vaccinations performed, of which no less than 81·0 per cent. succeeded, against 75·2 per cent. of re-vaccinations with fresh calf lymph, and 71·0 per cent. with humanized lymph.

Vaseline lymph was on its trial during the year, and the officiating Deputy Sanitary Commissioner in his report states that the results obtained with it fully justify the hopes entertained of it. It seems, however, impossible to agree with this opinion, for not only was the percentage of success attained in primary cases lower than where other kinds of lymph were used, but the marks resulting from the vaccination were not satisfactory. The fact that the marks are not pitted probably signifies only that the inflammation was so great that the septa were broken down; but a high degree of inflammation, even if it does not interfere with the efficacy of the prophylactic, is very undesirable in itself. Moreover, it will be remembered that the mortality of persons attacked by small-pox who

have good marks of vaccination is much less than half that of persons on whom the marks are, from whatever cause, imperfect. While it is, of course, common enough for the patient to develope a nasty sore from the introduction of extraneous organisms when scratching, it appears that the vaseline vaccine is highly putrescible, for in accounting for numerous failures it is stated that "vaseline lymph is a putrescible substance and unless all instruments introduced into the tube are properly sterilized each time, decomposition is readily set up, and the lymph becomes bad."

In the figures from the Central Provinces the feudatory states of Bamra and Sonepur are excluded, but particulars regarding vaccination in the State of Bastar have been included for the first time. The supervising staff, besides the Sanitary Commissioner, consisted of 19 Civil Surgeons and 28 Native Superintendents, and the average number of vaccinators employed was 260, including 51 in the feudatory states. The total number of operations performed was 397,036—a decrease of 52,684 as compared with the previous year. The falling off was common to British territory and to the feudatory states; and to primary operations decrease 30,762, and to re-vaccinations, decrease 21,922. Many causes contributed to hamper the work of vaccination in the province: (*a*) a diminished birth-rate consequent on the scarcity from which the northern districts have suffered for the past three years; (*b*) the establishment of famine conditions in 14 out of the 18 districts during the cold months, November to March, when the most of the work is done; (*c*) the vagrancy induced by the pressure of distress; and (*d*) the withdrawal of vaccinators from their ordinary work for duty in connection with famine and plague. The provincial establishment vaccinated 294,101 persons primarily, and 96 per cent. of the operations are said to have succeeded; they re-vaccinated 33,356, and of these operations 71·7 per cent. succeeded. In the feudatory states 97·2 per cent. of 57,051 vaccinations and 96·0 per cent. of 10,452 re-vaccinations are stated to have been successful. In spite of high ratios claimed in the native states, raising the general average percentage of success in primary operations to 96·2 and in re-vaccinations to 77·68, the figures are lower than in 1895-6, when 96·37 of the primary operations and 82·11 of the re-vaccinations succeeded. The average numbers of operations performed per vaccinator were, in British territory, 1,557 and in the feudatory states 1,564, decreases, respectively, of 208 and 267.

By the dispensary staffs, 15,027 primary operations and 1,746 re-vaccinations were performed, and 90·99 and 72·39 per cent., respectively, succeeded. The percentage of the estimated number of children born who were protected during the year was 47·5, against 49·3 in 1895-6, and 52·9, the mean of the previous three years.

Inspections suffered in the same way as operations from the interference of more urgent work. Civil Surgeons inspected 15·78 per cent. of the total number of operations and native Superintendents 50·24 per cent., against 18·5 and 51·13, respectively, in 1895-6. The percentage of success verified by the former was 92·01, and by the latter 93·46.

During the year, the Inspector General of Education issued a circular letter to the Inspectors of Schools urging them to enforce "with great strictness" the provisions of Articles 101 (*c*) and 268 of the Educational Code, and to ascertain whether scholars have been protected or not on the occasions of examinations in gymnastics, etc., and when passing them for grants.

The bulk of the vaccinations was carried on by means of animal lymph against the use of which there is said to be no prejudice worth noticing. Altogether 9,844 calves were operated on; of these, in 711 the vaccination failed to take, and 209 had to be rejected on account of excessive inflammation or suppuration of vesicles—a total failure of nearly one in ten. From the lymph obtained from the remainder, 240,217 children were vaccinated, and 94 per cent. of the operations succeeded.

The strength of the Department in Berar remained unchanged and consisted of the Sanitary Commissioner, seven Native Supervisors and 44 vaccinators. The total number of operations performed was 120,111, a number only twice exceeded in the last twelve years. The number of operations performed by each vaccinator rose from 2,423 in 1895–96, to 2,729 in the year under report. The number of primary operations was 98,594 and of re-vaccinations 21,717, and success was obtained in 96·8 and 20·5 per cent. of the cases respectively, as compared with 95·9 and 23·4 in the previous year. The percentage protected of the estimated number of infants born was 66·8, against 58·2 in 1895-96, and 60·9, the mean of the preceding three years.

Inspections were made at the rate of 1·6 per cent. by the Sanitary Commissioner and 55·8 per cent. by native Superintendents, the ratios of success verified being 97·0 and 95·2 per cent., as compared with 96·8 per cent. reported by the vaccinators. Dr. Little

explains that he finds a higher ratio of success than the Superintendents, because most of the cases which the latter discovered to be unsuccessful have been re-vaccinated before he sees them, and suggests, as an explanation of the ratios of success discovered by Inspectors being higher than that claimed by operators—a phenomenon observable in the returns of the Basim district of Berar, and in other provinces besides Berar,—that the vaccinators calculated on the total number of operations counting unknown cases as failures, whereas the results of all cases seen by the inspecting officers are, of course, known ; the excluded percentage of success among unknown cases accounting for the difference. The Compulsory Vaccination Act was introduced into the town of Karinja during the year and is now in force in all the municipalities.

The use of animal lymph is now universal throughout Berar, to the entire exclusion of the arm-to-arm method. Dr. Little gives an account of the methods adopted by him, quoted, not only because of the interest of the passage, but because of the success which has attended the work in Berar.

" Since I first entered upon the duties of the Sanitary Commissioner's office in October 1878, animal " lymph obtained from the cow has been more or less used in the province. It was first tried for " the purpose of renewing our supply and starting the season's operations, and we were thus able to " dispense with the annual supplies of English lymph furnished by Government, for this purpose. " The procedure in this respect followed in Berar was brought to the notice of other Governments and " Administrations—*vide* paragraph 4 of Home Department No. 68, dated 8th March 1882.

" After a time, when Superintendents and Vaccinators became more skilled and experienced in " animal vaccination, the work of the province came to be carried on partly with animal and partly " with humanized lymph until 1890, when a scare was raised as to the possibility of transmitting " leprosy through the medium of humanized lymph. Arm-to-arm vaccination was then completely " abandoned, and the work carried on entirely with lymph propagated from the cow or buffalo. The " people of the province were by this time quite accustomed to the idea of cow vaccination, which " had been thus gradually and quietly introduced, and there was no difficulty experienced in " substituting animal for humanized lymph ; indeed, native feeling has come to prefer the animal " lymph, for they were quick to perceive that their children suffered less when cow lymph was used ; " that it either took or failed without subsequent ulceration, whereas the arm-to arm method in the " hands of a careless vaccinator not infrequently resulted in severe ulceration and inflammation of the " child's arm. Over and over again have the villagers told me this, and personally I seldom or ever " see now the ulcerated and inflamed arms which were but too common under the old arm-to-arm " system as practised by uneducated and unprofessional men at a distance from immediate " supervision.

" Another point in favour of animal lymph, in public estimation, was that calf vaccination did " away with the necessity for a child being taken from one village to another for the purpose of " affording a lymph supply, or for the child of a high caste man being vaccinated from one of low " caste, both procedures being unpopular and often strongly objected to.

" In regard to religious prejudice, none was met with, though it is more than probable that had the " villagers not been gradually accustomed to see calves and buffaloes vaccinated, until it had become " quite a commonplace procedure, and had they not had time to realize the advantages to themselves " accruing from the use of animal lymph, I have no doubt objection would have been raised on one " ground or another.

" When the system of vaccination direct from the calf to the exclusion of the arm-to-arm method " was introduced, it was anticipated there would be some trouble in the procuring and feeding of the " calves ; but this has not proved to be the case, save in municipalities, where, owing to the difficulty " of procuring animals, the use of lanoline lymph has been recommended.

" Berar being entirely an agricultural province with large herds of cattle in most villages, there is " no difficulty, as a rule, in obtaining calves for vaccinating purposes. The village patel supplies the " vaccinator, on loan, with the animals required, receiving a receipt for the same, he, in his turn, " passing a receipt to the vaccinator when the calf is returned to him. Each vaccinator has a circle " assigned to him, averaging some 60,000 inhabitants, and is required to reside permanently in his " circle. This circle is sub-divided for vaccination purposes into small circles, each of which has to " be taken up systematically in rotation and protected, as far as possible, at the rate of 40 per 1,000 of " the population. Before leaving one sub-division and going on to another, the vaccinator has to " report to his Superintendent and obtain his permission, which is not granted if the Superintendent " considers the rate of protection afforded insufficient. Under this arrangement District Superin- " tendents have systematic control over their men, and the vaccinator, or "*Devi Doctor*," as he is " called, comes to be well known to the people amongst whom he resides, and, if he is a good man, " soon gains their confidence and respect.

" At the close of the monsoon, generally about the end of September, each vaccinator is furnished " with a small quantity of lanoline paste lymph to start his supply, which is allowed to die out during " the rains. With the paste a few children are vaccinated, and when a successful result has been " obtained, a calf is inoculated from a child's arm, and vaccination then kept up from calf to calf or " renewed from a healthy child should it show signs of degenerating. The method of itineration is " as follows. On the result day, in a certain village, the vaccinator protects, as far as possible, all the " available children, and operates upon one or more calves ; these he distributes to the village or " villages he may have arranged to work in next, usually situated not more than three or four miles " distant, leaving the animal in charge of the patel, who tells off a *watandar dher** to look after it, " and to supply it with grass and water. Only weaned animals are used for vaccination purposes. " The vaccinator having fixed a bamboo collar to its neck to prevent it licking itself, goes off to

* Hereditary village Servant.

"another village, where he may have a result to record, or another calf ready to yield lymph for "vaccination. On the fifth day, or 96 hours as near as possible from date of operation, he returns to "inspect the calf, and if the result is successful, which is usually the case, he has the children "collected and proceeds to vaccinate them, first cleansing the shaven part of the calf with warm water "as well as the children's arms—at least he should do so—though this part of the procedure is, I am "afraid, often neglected. Sometimes, when villages are close together, a calf can be taken from one "to the other on the result day; but if taken any distance, the vesicles get rubbed.

"In this way, some vaccinators in the height of the working season have a calf result every "day of the week, or at least one every other day, which can generally be managed by little "arrangement.

"It will thus be seen that nothing is paid by the department for either the hire or feed of the "calves, and no difficulty up to now has, as a rule, been experienced in procuring any number of "animals save in municipalities, where the work will in future be carried on with lanoline paste "lymph."

The supervising staff in Madras Presidency was made up of one Deputy Sanitary Commissioner and 59 Deputy Inspectors, and Civil Surgeons carried on inspections in their districts. The average number of vaccinators was 834. Although the number of operators was eight less than in the previous year, the number of operations performed rose from 1,178,970 in 1895–96 to 1,234,350 in 1896–97, and the number of vaccinations performed by each man from 1,383 to 1,465. Of the total number of operations, 1,161,127 were primary and 73,223 were re-vaccinations, the percentages of success reported being 92·6 and 80·2, respectively, as compared with 87 and 80·5 in the preceding year. In consequence of its having been made optional for the medical officers attached to dispensaries to carry on vaccination, there has been a progressive decline of late years in the numbers vaccinated by the dispensary staffs. The number vaccinated by them in 1894–95 was 26,410; in 1895–96 the number fell to 19,201; and in the year under report there was a further fall to 13,370. Of these 12,004 were primary vaccinations, successful at the rate of 88 per cent.,—a ratio, in the opinion of the Deputy Sanitary Commissioner, approximating to the degree of success generally attainable in the presidency; and 1,366 were re-vaccinations, of which 74·8 per cent. were successful.

The percentage of the estimated number of children protected was 23·2 against 22·0 in the previous year, and 18·6, the mean of the previous three years.

Of the total number of vaccinations performed, 2·5 per cent. were verified by Civil Surgeons and 49·8 per cent. by native Superintendents and others. The ratios of success found by these officers were practically the same as last year,—90·8 and 89·5 per cent., respectively, as compared with 92·0 per cent. reported by vaccinators.

Except in 226 cases vaccinated in Ganjam, with humanized lymph, the vaccine used was derived from the calf and was applied (*a*) direct, (*b*) in tubes without admixture, (*c*) in tubes with glycerine added, and (*d*) in tubes with lanoline added. In the following table the results obtained with the various vaccines are given :—

	Number of cases.	Percentage of success.
(*a*) Lymph taken direct from arm to arm	287,225	97·2
(*b*) Lymph in tubes or plates	118,695	94·6
(*c*) Lymph in tubes with glycerine	649,700	88·9
(*d*) Lymph in tubes with lanoline	68,471	94·0

The lymph sent out in tubes and plates without admixture was invariably used at once, which accounts for the high ratio of success attained with it.

The vaccination staff under the Civil Surgeon of Coorg consisted of one Native Inspector and eight vaccinators. There was a slight falling off in the number of operations as compared with the previous year : 10,006 having been performed against 10,411, and the number of persons vaccinated by each operator fell from 1,157 to 1,112. Of the total, 8,717 were primary operations, and 1,289 were re-vaccinations; the percentages of success attained were 96·81 and 89·76, respectively, as compared with 95·72 and 86·27 in 1895–96. Besides these, 505 operations were performed by the dispensary staff; 52·07 of 363 primary operations and 21·13 per cent. of re-vaccinations were successful. The percentage protected of the estimated number of children born was 18·6, against 17·2 in 1895–96, and 13·3, the mean of the previous three years. Vaccinations were performed with calf lymph. The cost of the establishment rose from Rs. 2,600 in 1895–96 to Rs. 2,790 in 1896–97, and the cost of each successful case from four annas and one pie, to four annas and eight pies.

In Bombay Presidency the supervising staff consisted of five Deputy Sanitary Commissioners, and 45 Inspectors of Sanitation and Vaccination and the average

number of vaccinators was 437, inclusive of 78 employed in native state territory. Besides these there were employed 16 clerks and 512 peons. The total number of operations was 802,738, against 803,850 in 1895–96, and the average number performed by each operator was 1,834, or 20 less than in the previous year. The decrease is attributed to the outbreak of plague in Bombay and to the occurrence of floods in Sind. Of the total number of operations 732,893 were primary, of which 92·19 per cent. succeeded, against 93·25 in 1895–96; and 69,845 were re-vaccinations, of which 59·64 per cent. were successful, as compared with 57·59 per cent. in the previous year. Besides these, 1,344 primary operations, of which 85·67 per cent. succeeded, and 905 re-vaccinations with success in 76·13 per cent., were performed by the establishments of dispensaries. Of the estimated number of children born, 59·1 per cent. were protected, as compared with 58·0 per cent. in the previous year, and 56·2 per cent., the mean of the preceding three years. The percentages of cases verified by Deputy Sanitary Commissioners and Native Inspectors were smaller than in the previous year,—4·74 and 36·42 as compared with 7·03 and 37·67, and the proportions of cases found by them to be successful were also less, 80·9 and 97·1 per cent., against 95·55 and 99·01.

Bovine lymph was exclusively used throughout the year in the city of Bombay; and elsewhere it was used in selected areas.

In the native states of Baroda, Cutch, Kathiawar, Palanpur and Idar, 212,474 primary operations and 8,320 re-vaccinations were performed with success, respectively, at the rates of 94·13 and 69·5 per cent. The number of infants protected in these states fell from 162,069 in 1895–96, to 161,514.

In Lower Burma the vaccination staff consisted of 10 Native Superintendents and 110 vaccinators. The number of operations rose from 242,845 in 1895-96 to 288,381, and the average number performed by each man from 1,974 to 2,622. The increase in the work was distributed throughout the province, except in the Arakan Hill Tracts, the district of Akyab, and the town of Rangoon. The falling off is attributed, in the Hill Tracts to the inefficiency of the vaccinator; in the Akyab District, to inefficient supervision; and in Rangoon town, to an unfortunate occurrence which led to the prohibition by the President of the Municipality of the compulsory vaccination of coolie immigrants who have furnished by far the largest proportion of cases in past years. The President's order resulted from the death from tetanus after vaccination of a gardener in the employment of the German Club. The attack of tetanus from which the gardener died does not appear to have been due to the vaccination, but to his having applied a paste of leaves and earth to the vesicles. The orders issued, however, produced such a feeling of alarm in the popular mind that no adult coolies could be induced to submit to vaccination.

Of 267,146 primary operations, and 21,235 re-vaccinations, 92·01 and 58·79 per cent., respectively, succeeded, against 91·21 and 46·01 in the previous year. The establishments attached to dispensaries performed 1,735 primary operations, and 276 re-vaccinations, of which 94·58 and 44·63 per cent. succeeded. The relatively large number of re-vaccinations was due to the performance of 2,146 in the district of Hanthawaddy, where there was a great deal of small-pox.

The ratio of infants protected was 34·3 per cent. of the estimated number of births, as compared with 22·0 per cent. in 1895–96, and 14·2, the mean of the previous three years. The percentages of the total number of operations verified by Civil Surgeons and Native Superintendents were somewhat higher than in the previous year—15·93 and 24·6 respectively, against 14·61 and 18·13.

In Upper Burma, the staff consisted of the Civil Surgeons, one Native Superintendent and 51 vaccinators. The number of operations performed was 126,464—a satisfactory increase as compared with 1895–96, when the figure was 115,703. The average number performed by each vaccinator rose from 2,143 to 2,480. Of 123,520 primary operations and 2,944 re-vaccinations, 93·34 and 64·64 per cent., respectively, were successful, as compared with percentages of 92·67 and 66·65 in the previous year. The staffs of dispensaries were successful in 89·06 per cent. of 3,731 primary operations and in 65·22 per cent. of 161 re-vaccinations. There were 41,295 infants protected during the year as compared with 30,741 in the previous year. The percentage of operations inspected by Civil Surgeons was 33·58, and by the Native Superintendent, 10·18.

Vaccination in the Shan States continues in a very backward condition; only 4,401 operations were performed by vaccinators and 158 by the dispensary staff—all primary. The instruction of the *sayas*, or native doctors, was discontinued in the Southern States towards the end of 1896, as it was found impossible to check their work, and a proposal to instruct the same class in the Northern States was rejected, because, as a rule, the *sayas*

are lazy and untrustworthy. The entertainment of additional travelling vaccinators in the Southern States has been sanctioned, and an improvement in the results obtained may be anticipated.

Lymph paste was obtained from Bangalore and was manufactured locally;—the pastes made in Rangoon and in Taunggyi being very satisfactory.

The staff in Ajmere-Merwara consisted of two Superintendents and 13 vaccinators—one more vaccinator than in 1895–96. The total number of operations rose from 15,978 in the preceding year, to 16,282, but the average number of operations performed by each vaccinator fell from 1,331 to 1,252. Of the total, 15,962 were primary operations and 320 were re-vaccinations, successful at the rates of 96·82 and 75·62 per cent., respectively. The ratio of infants protected was 51·3 per cent. of the estimated births, as compared with 46·3 per cent. in the previous year and an average of 40·5 per cent. in the preceding three years.

Civil Sanitary Works.

During the year under review, sanitary improvements in very many, if not in the majority, of the towns had to be postponed or curtailed on account of impending scarcity. As some compensation for this, there may be reckoned the excavation in many districts by relief workers of numerous tanks and wells, most of which will prove of permanent advantage to the people.

While it is satisfactory to note that improvement, especially in the direction of water-supply schemes, is on the whole steady, it seems to be doubtful if the very best results possible from the money expended are always obtained. An examination of the mortuary statistics of towns before and after the introduction of new water-supplies shews that the death-rates are not always reduced in the degree that might be expected; and that, in some towns, the mortality has been *apparently* greater after the introduction of the new supply than it had been before. The increased death-rates can be easily shewn in most cases to be due to improved registration, an improvement naturally coincident with the greater interest given to sanitary affairs. But when the good results that might be looked for do not follow the introduction of a new supply, it is not sufficient to give the comforting explanation that improvement has taken place in the registration of deaths; this may be the case, but very careful enquiry into all possible causes of increased mortality should be undertaken. There may be no real improvement in the quality of water consumed, or some condition detrimental to the public health may have accompanied the introduction of an improved supply of water. In most of the towns, it may be concluded from the amount of water per head that is taken from the works, that a mixed supply is being used; and this is an unmixed evil, for the old sources of water are much less likely to be conserved than they were before the introduction of new supplies. It may be that sufficient care is not bestowed upon the works, and that the water when it reaches the public has been improperly filtered. A municipality may spend lakhs of rupees on a catchment area and in providing reservoirs, filter-beds, mains and stand-posts, but give no attention to the upkeep of the works. Water-supply works require expert management, and to entrust their control to a man who knows nothing of hydraulics and less about the delicate working of a filter-bed is to court disaster, however skilfully and economically the pumping engines may be managed. Again, drainage may be at fault, where a greatly increased quantity of water is brought into a town before adequate means to remove it have been provided.

The most hopeful sanitary advance during the year, then, is the reconstitution of the Sanitary Boards in Bengal and in the North-Western Provinces. A properly constituted Sanitary Board, endowed with sufficient control over municipal bodies, will ensure continuity of work undertaken, and so prevent the introduction of schemes to bring water into towns before sufficient means for its removal exists; and they will not permit municipal councils to allow works in which large capitals have been sunk to prove useless, or even dangerous, from want of efficient supervision.

As explained in the Report for 1895, the figures relating to expenditure on sanitary works in Bengal have reference not to the calendar year but to the official year ending with the 31st of March. This change was made in 1895, in order that comparison with similar figures, furnished in reports on municipal administration, might be more easy.

Omitting Calcutta, the number of municipalities in Bengal in 1895–96, was 145, or one less than in the previous year, but the total income, including the opening balances in

both cases, rose from Rs. 45,53,651 in 1894–95, to Rs. 46,02,679 in the year under review. Of this total, 52·79 per cent. was spent on original and recurring sanitary works, 9·03 per cent. on roads, 4·52 per cent. on the public safety, and 23·40 per cent. on other requirements. Under the three principal heads of expenditure, the totals were Rs. 9,96,441 on water-supply, Rs. 8,88,026 on conservancy, and Rs. 1,49,559 on drainage. As compared with 1894–95, there was a substantial increase of R1,98,832 devoted to water-supply, and a slight increase in the cost of conservancy, while the large decrease of Rs. 1,24,182 in the expenditure on drainage was due to inclusion in the total of the former year of Rs. 1,08,768 on account of the Patna drainage scheme, on which, in 1895–96 only Rs. 4,874 were spent.

The average proportion of income spent on original works was 5·03 per cent. In seventeen municipalities, including Jalpaiguri (34·84), Tittagarh (29·36), and Cossipore-Chitpur (19·06), where the highest proportions were expended, more than 10 per cent. of the municipal income was thus disposed of, while in 28, nothing at all was so spent. The average expenditure on recurring sanitary works was 37·64 per cent., ranging from 61·81 in English Bazar, in Malda, to 4·56 in Joynagar.

The most important sanitary business of the year were the completion of the Howrah water-supply works, which were opened in February 1896 by Sir Alexander Mackenzie; the completion of the Muzaffarpur drainage scheme; the extension of the Cossipore Chitpur water-supply; additions of the Serampore and Jalpaiguri drainage works; and the improvement of the water-supply, and the construction of drains, at Bhagalpur.

Nightsoil is trenched in most places on improved principles; but the cultivation of the trenching grounds does not seem to receive the attention from the municipal authorities which its importance demands. Dr. Dyson suggests that municipalities should be required to cultivate these grounds and exhibit the crops on market days in order to shew the superiority of the produce of the highly manured land. He suggests also that the municipal cultivator, should, in addition to his pay, get a percentage on the sale of the produce.

While the expenditure on sanitary works in rural areas amounted to Rs. 1,42,012 against Rs. 1,03,912 in the previous year, but little advance has, it is stated, been made in rural sanitation. Owing, however, to the deficient rain-fall and the consequently impending scarcity, numerous tanks and wells were dug, many of which will, no doubt, prove of lasting benefit to the localities in which they have been made. The sum provided by private generosity for sanitation, which in 1894–95 amounted to Rs. 1,88,875, rose to Rs. 4,94,131.

During the year the Sanitary Board was strengthened by the addition to its membership of the Chief Engineer to Government in the Public Works Department, and was composed as follows:—

The Member of the Board of Revenue in charge of miscellaneous revenue ...	*President.*
The Chief Engineer to Government in the Public Works Department	*Members.*
The Chief Engineer to Government in the Irrigation Department	
The Sanitary Commissioner	

with the Sanitary Engineer as Secretary. Not only was the Board strengthened but its functions were enlarged, and it has been ordered that all schemes relating to sanitary works should be referred to the Board for approval. The importance of such an enhancement of the scope of the work of the Board cannot be over-rated, and calls for imitation in other provinces, especially in those in which no Sanitary Engineer has as yet been specially appointed.

There was the usual difficulty in holding meetings of the Board owing to the absence of members from head-quarters, and business had to be carried on by circulation of papers.

The principal projects with which the members dealt were the following:—

(1) A scheme estimated to cost Rs. 33,232, for improving the drainage of Krishnagar by the excavation of the Anjuna Khal.

(2) The Berhampore water-supply scheme, estimated to cost Rs. 2,38,883, was finally passed. This work, which is the gift of the late Maharani Surnamoyee, C.I., will, it is expected, be completed in 1897.

(3) A scheme for the supply of filtered water to the municipalities situated on the left bank of the Hooghly. The Board were obliged to recommend the abandonment of this project as the cost, owing to the provision of elevated reservoirs to ensure a constant supply and the scattered situation of the populations, was prohibitive.

(4) Schemes for draining the suburbs of Calcutta and remodelling the storm-water outfall, to cost Rs. 78,87,089, which were drawn up by Mr. A. H. Hughes, C.I.E., Engineer to the Corporation, were examined and approved.

(5) An alternative scheme, to cost Rs. 2,50,000, for the supply of drinking-water to Midnapore.

(6) An estimate for developing the existing distribution of water from the Howrah water-works.

(7) Estimates and plans for the supply of pure water to the town of Chittagong. The estimated cost of the scheme is Rs. 2,37,898, but the matter has been referred to the local officers for reconstruction of the scheme on lines indicated by the Sanitary Engineer to the Board.

(8) A scheme for the supply of pure water to Cuttack, at an estimated cost of Rs. 2,25,000; this had to be abandoned as beyond the means of the municipality.

The Board also gave opinions regarding a large number of miscellaneous subjects which were referred to them, and the Sanitary Engineer made many useful enquiries and inspections.

The total income in 1896 of the municipalities, towns, unions and stations in Assam, excluding the towns of Hailakandi, Sunamganj, Karimganj and Maulvi Bazar, which have no separate incomes of their own, amounted to Rs. 2,62,416. Of this sum Rs. 1,38,592, or 46·10 per cent., was spent on sanitary works, as compared with Rs. 1,15,175, or 44·13 per cent., of the total income thus expended in 1895. The highest percentage of municipal income devoted to sanitation was 71·37, spent in the small town of Mangaldai, the lowest 24·21, in the union of Jorhat.

As has frequently been noted, the towns of Assam are really populous straggling villages, built generally on level sites, so that any extensive schemes of water-supply or drainage must necessarily be expensive and beyond the means of comparatively poor communities.

In Gauhati and Shillong there are waterworks whence piped supplies of water are distributed in the municipal areas. A new pumping-engine was ordered for the works in Gauhati, but did not arrive, and during 1896, the old engine frequently broke down, owing, seemingly, to defects in the boiler, so that water was frequently not available from the works. In Shillong, some extension of the pipe-supply was made, and it is proposed to extend the station supply to the cantonment.

In the report for 1893, an account of the projected water-supply works at Sylhet was given. It was intended to sink wells on a suitable site, and to pump water from them to an elevated reservoir whence, after proper filtration, it would be distributed by pipes and hydrants. It appears, however, that this scheme was unsuitable, and the following remarks regarding it are taken from the Resolution, published by order of the Chief Commissioner which accompanies the report of the Sanitary Commissioner :—

"The first of these wells has recently been completed at a cost of Rs. 7,700, the work of "construction having lasted for several years. Mr. Cotton's attention was drawn to the matter while "on tour in Sylhet, and he ascertained that the scheme, if completed, would involve a capital "expenditure of nearly two lakhs of rupees, to say nothing of the cost of maintenance. A town of "the size of Sylhet, containing only 15,000 inhabitants, is too poor to be able to construct or maintain "water-works on such a scale, and the Chief Commissioner has, therefore suspended further "operations in connection with the scheme while pointing out other means for improving the water-"supply of the town at a cost within the means of the inhabitants."

In many towns, wells have been constructed, but the inhabitants decline to drink water from them, preferring water from rivers and tanks. It is generally impossible to prevent the pollution of rivers, and the Sanitary Commissioner seems to be of opinion that the best method of improving the water-supply is to protect the tanks and make arrangements to pump the water from them into reservoirs, from which it can be drawn off by means of taps.

Silchar, Manipur and Fort Aijal are the only places where excreta are destroyed by fire —this, it appears, can be successfully done by means of Young's incinerator. In other towns, the trenching system is in force, and is stated to be satisfactory only when carefully carried out in places where the trenches are not liable to be flooded during the rainy season. In rural areas, no sanitary work of any magnitude was begun, but a large number of masonry wells were sunk, old wells were cleaned, and tanks were repaired. It has for some time past been the policy in Assam to discourage the excavation of tanks and insist on the construction of masonry wells for the provision of drinking water. But, as already stated, the people greatly prefer tanks to wells, and, as it is impossible to exercise proper supervision over either tanks or wells in rural areas, the

Chief Commissioner, after considering all the arguments for and against tanks as a source of water-supply, has decided to remove the absolute prohibition against the digging of tanks, leaving it to the discretion of Local Boards to carry out the measures in their opinion best suited to the locality concerned.

"The Sanitary Board did not meet during the year."

The income of the 103 municipal towns in the North-Western Provinces and Oudh, in 1895–96, excluding opening balances, was Rs. 52,92,870, as compared with Rs. 55,06,002 in the previous year. Although the income was slightly less than in 1894–95, the expenditure on sanitary works, except for conservancy, markets, etc., was greater; on water-supply Rs. 10,97,305, against Rs. 8,29,523; on conservancy, Rs. 8,88,488, against Rs. 8,97,945; on drainage, Rs. 4,30,079, against Rs. 3,42,500; and on markets and slaughter-houses Rs. 47,723, against Rs. 56,432.

There are several large municipal towns in the provinces, namely, Agra, Allahabad, Benares, Cawnpore, Lucknow, Meerut and Bareilly, and all, except Bareilly, have now been furnished with complete water-supply works, varying in cost from Rs. 25,62,000 at Benares, to Rs. 7,40,000 at Meerut, all met from loans advanced by Government, to be repaid with interest by sixty half-yearly instalments. In each of these towns, an Engineer has been employed to carry out and maintain the works, and to give effect to any extensions which may be necessary. The Meerut Board have dispensed with the services of their Engineer from 1st April, and placed the control of the water-works in charge of the Superintendent, an experiment which the Sanitary Engineer of the province notes, "will "be watched with every care, and some amount of interest."

Two hill stations of Mussoorie and Naini Tal have also pumped water-supplies, and the works have been supervised by the Municipal Secretaries who, as a rule, have also been engineers, "but the results seem to indicate that some better and more efficient professional "control is required." It is in contemplation to appoint a Superintendent of Machinery for the provinces; the need for having such an officer to supervise the working of the different pumping engines has been apparent during the year, but the demands of famine works have necessitated too rigid economy in every direction to admit of an appointment being made.

The Meerut water-works were opened early in 1896, and the supply was available for general use from the 6th of May. The original estimate of Rs. 8,00,000 was reduced to Rs. 7,50,000, and the actual expenditure will probably be less. During 227 days the supply amounted to 73,238,631 gallons, equal to 4·55 gallons per head per diem. The character of the supply is good, although, owing to one filter being carelessly worked, 3,000 microbes in a c.c. were on one occasion present. The average of a large number of samples from that filter, however, was only 25·8 microbes in the c.c., and in samples from other filters even less. Only one house connection was made.

The Dehra-Rajpur works were completed in the beginning of the hot weather. This is a gravitation supply from the springs half way up to Mussoorie. The estimated cost was Rs. 97,241, but, owing to a favourable rate of exchange, the actual cost was only Rs. 93,100.

At Benares, 628,846,304 gallons were supplied, equal to 8·12 gallons per head, against 7·5 gallons in 1895. The number of house-connections is 3,887. The character of the supply was good. A raised reservoir, estimated to cost Rs. 78,036, was commenced just before the rains, and is rapidly approaching completion. The reservoir wil hold 250,000 gallons, and will give an initial head of pressure between 71 and 56 feet.

At Lucknow, 391,309,106 gallons were supplied, equal to 2·95 gallons per head, a slightly increased consumption as compared with 1895, when it was 2·6 per head. There are practically no house-connections. The supply was generally good. A raised reservoir to hold 250,000 gallons, and giving a head at the filtering station, where it has been erected, of from 53 to 42 feet, was finished at a cost of Rs. 60,255. Several extensions of the water-supply, notably to the Chauk and Daulatganj wards, were made.

At Cawnpore, 391,309,196 gallons were delivered, equal to 7·5 gallons per head, considerably less than in 1895, when the average consumption was 8·41 gallons. The number of house-connections was 93, and about 35 miles of drains were flushed daily. The quality of the water was good.

At Allahabad, 580,024,042 gallons were supplied, or 10 gallons a head, against 8 in the previous year. There were 1,430 house-connections, and over 16 miles of drains were flushed daily. The supply was generally good, although on two occasions it was reported that a microbe believed to be that of enteric fever was detected in the filters. An investigation was made in both instances, and the result reported to Government.

The extension of the water-supply to Daraganj and the site of the fairs, was under construction.

At Agra, 569,406,613 gallons of water were supplied, or 10·5 gallons per head per diem, against 8 in the previous year. Thirty-four house-connections were made, bringing the total to 597. The water was of good quality.

At Naini Tal the amount of water delivered could not be exactly estimated, but it is stated to have been quite inadequate to the requirements, and the pumping arrangements were faulty. A new scheme has been adopted.

At Mussoorie, 6·4 gallons per head were supplied daily. There was no house-connections and the drains are not flushed.

The cost of delivering 1,000 gallons of filtered water in 1896–97 was rather more than $1\frac{1}{2}$ annas in Agra. Allahabad and Benares; just over 2 annas in Cawnpore and Lucknow; $2\frac{3}{4}$ annas at Meerut, where the cost is expected to fall; the cost at Mussoorie is not known, and at Naini Tal it was just under a rupee.

A preliminary rough estimate, amounting to Rs. 7,00,000, for works at Bareilly was considerably beyond the resources of the municipality. Water-supply projects for Farukhabad-Fatehgarh, Fyzabad-Ajudhia and Jhansi are in contemplation.

The sewerage and drainage scheme at Benares is by far the largest and most expensive which has been undertaken in the province. The total cost is estimated at Rs. 19,40,000, and work to the value of Rs. 6,00,327 has been completed. The main sewer, outfall, and subsidiary works were expected to be completed early in 1897, and branch sewers in the unsewered area later in the year. Owing to financial pressure, part of the work has been postponed, and, in the meantime, a programme of the work to be taken up year by year has been drawn up.

At Cawnpore, the greater portion of the scheme for the *Sadar Bazar* was completed, but there was practically no progress made with the main project for the city.

At Agra, the paving and draining of *Muhallas* is being continued. Estimates and plans for an intercepting sewer, to run along the river bank, and so cut off the eight main drains which at present run right into the river, were prepared and are being considered.

At Mussoorie, a scheme estimated to cost Rs. 40,000, for a sewage shoot and farm is being carried out. So far only Rs. 19,449, for land and pipes, which are now at the site, have been spent, as, owing to defective preliminary arrangements, the work was not begun.

At Kasganj, in the Etah district, a scheme for improvement of the drainage was completed.

At Hardwar, a four-celled incinerator on the Garlick type was completed, but the working of it, probably on account of lax supervision, has not been satisfactory. It was reported that in 84 days 1,334 maunds of nightsoil were consumed, with an expenditure of 2,200 maunds of fuel, to which 2,388 maunds of street sweepings were added, the cost being about $4\frac{1}{2}$ annas per maund of filth, which is excessive. It is hoped that care in the use of fuel and a better way of treating the nightsoil before it is burned, may prove more economical.

Drainage schemes for Bareilly, Fyzabad-Ajudhia, Farukhabad, Jhansi, Pilibhit, Dehra, Hathras, Saharanpore, Muzaffarnagar, Aligarh, Deoband and Hardwar have been proposed or are in contemplation.

Many improvements were carried out in rural areas, and although the circumstances of the year were not favourable to the execution schemes of sanitary improvements through the ordinary staff who were otherwise fully occupied, the relief-works undertaken in the neighbourhood of many villages will prove of permanent benefit.

During the year the Sanitary Board was reconstituted, and converted from a consultative into an executive body; funds were placed at its disposal, and definite functions delegated to it. The resolution* by the Local Government in which these changes are ordered deals with the reorganization of the sanitary service of the province generally, and from the sanitary point of view is one of the most important ever issued by a Local Government in India.

There were three meetings of the Sanitary Board during the year, two at Naini Tal under the old organization, and one at Lucknow, of the reconstituted Board. The following were among the subjects considered at the first two meetings:—

(1) The report of the Provincial Sanitary Commissioner for 1895; attention was specially drawn to remarks on defective registration.

---

* See Appendix A, p. 141.

(2) The final draft of a letter to the Local Government, containing the Board's opinion on the best method of maintaining village sanitary records, was approved.

(3) The attention of the Board was called to delay in extending the water-supply of Allahabad to Daraganj, and the delay brought by them to the notice of Government, with the best results.

(4) The abnormally heavy mortality in the small town of Baghpat and Deoband. The Board deputed the Sanitary Commissioner and the Sanitary Engineer to make enquiries on the spot.

The new Board met at Lucknow on the 23rd November 1896.

1. It was arranged to obtain from Commissioners, lists of sanitary works contemplated in the various divisions.
2. It was decided to ask Government for an increase of strength, and reorganization of the pay, of registration clerks in each district.
3. The Sanitary Commissioner's instructions to Civil Surgeons regarding the regrouping of registration circles were approved.
4. It was decided to ask Government what funds would be placed at the Board's disposal during the coming year.
5. A proposal of the Chemical Examiner to discontinue the chemical analyses of municipal water-supplies in favour of bacteriological analyses alone was negatived, as the former were considered quite as valuable as the latter for the purposes for which the examinations are made.

The income of the municipal towns in the Punjab in 1896, including an opening credit balance of Rs. 12,28,318, was Rs. 53,98,100, against Rs. 55,30,673 in the previous year. Of the total, Rs. 12,36,690 was devoted to sanitary works, against Rs. 12,33,037 in 1895. Under the three main headings, water-supply, drainage, and conservancy, sums, respectively, of Rs. 1,66,744, Rs. 1,26,608, and Rs. 5,83,174 were expended.

The amount realised from the sale of manure and town sweepings was Rs. 1,36,076, which, although upwards of Rs. 3,000 less than in 1895, was a larger sum than those obtained in previous years.

During the year the Haripur water-supply scheme was completed at a cost of Rs. 43,000. The piped water-supply of Kohat was extended to the small village of Chillarkot close to the cantonments. The project for the water-supply of Bhiwani, in the Hissar district, was begun. Some progress was made with the Ludhiana scheme, while that for the supply of Ferozepore cantonment was considered.

In Delhi, a portion of the drainage scheme was completed, and estimates for the remainder were sanctioned. Drainage projects for Lahore, Mooltan, Gujranwala, Rawalpindi and Hazro were in process of being carried out ; estimates for schemes for Ladwa, Umballa, Ferozepore and Fazilka were under consideration ; and similar estimates for Gurdaspur, Gujrat and Jagraon were prepared.

In the Delhi district, the construction of a filth trenching farm was begun. The area is about 250 acres situated south of the city of Delhi. This area is divided into three plots, one of which will be trenched, while a second is lying fallow and the third cultivated.

The Sanitary Board met twice during the year, and considered the following subjects :—

1. Correspondence in connection with the Ferozepore City and Cantonment Drainage Scheme, with a note by the Secretary to the Board, shewing what further progress had been made in the matter since July 1894.
2. Statements, drawn up by Mr. E. Oliver, when officiating as Chief Engineer, in which he described the sanitary condition of the municipal towns, and suggested improvements. Copies of these statements were sent to the local officers concerned with enquiries as to how far they were in a position to carry out the suggested improvements.
3. The progress report of sanitary reforms, regarding which the Board recorded their opinion that minor sanitary works had progressed very satisfactorily.
4. The prevalence of fever in the province, specially in swampy and water-logged areas, and the remedies that might be applied.

The income of the nineteen *Sadar* towns in the Central Provinces in 1896 was Rs. 16,26,680, and, excluding sums aggregating Rs. 80,778, which were spent on medical relief, vaccination and miscellaneous works, Rs. 2,79,252 were spent on sanitation, including

Rs. 52,420 on water-supplies, against Rs. 50,449 in 1895 ; Rs. 2,05,089 on conservancy, against Rs. 1,95,861, and Rs. 16,895 on buildings against Rs. 32,586.

The most important works carried out and in contemplation during the year were the following :—

Wardha.—The estimate prepared in 1895 for a scheme to supply the town with water by pumping from the river Paunar, was considered in May 1896. It was resolved to modify the scheme so as to include a service reservoir and so avoid pumping the water into the mains direct from the filtering stations.

Bhandara.—An estimate, amounting to Rs. 1,85,434, to supply the town with water by pumping from the river Wainganga was considered, and sanction was given to the preparation of a final estimate.

Jubbulpore.—Further progress was made with the completion of the water-supply works, on which about Rs. 32,000 was expended during the year.

Harda.—The experimental wells, begun in 1895, were finished, as well as filtration and sump wells, and a preliminary estimate for Rs. 19,575, to pay for lands occupied, head-works and approach roads, was sanctioned.

Khandwa.—The water-supply works were practically completed, and pipes were laid in the town at a total cost of Rs. 3,01,302.

A survey for a water-supply scheme for Chhindwara was completed ; a preliminary survey was undertaken at Bilaspur ; and, at Hoshangabad, a water-supply scheme on a small scale was under consideration.

Plans and estimates for a main out-fall drain for Jubbulpore City were approved, and a drainage scheme for Wardha was under consideration.

Considerable sums were realised by many of the towns from the sale of nightsoil, or from the lease of the lands in which it had been deposited.

The Sanitary Commissioner is the President of the Board, and the members are the Commissioners and certain district officials of the division in which a meeting is held. There were four meetings during the year, at Nagpur, Raipur, Jubbulpore and Pachmarhi, when proposals and estimates for schemes of sanitary improvement in the various districts were considered.

The total estimated income of the municipalities in Berar was Rs. 2,42,922, of which 74·2 per cent. was allotted for Sanitary Works and Rs. 1,70,515, or nearly 95 per cent. of the allotment, was actually spent as follows :—On water-supply, Rs. 71,180 ; on conservancy, Rs. 59,988 ; on drainage, Rs. 10,208 ; and on other sanitary works, Rs. 29,139.

No new work of magnitude was undertaken, but the Kapsi water-supply scheme for Akola was completed at an expenditure during 1896 of Rs. 35,598.

The year was a very dry one, and Dr. Little made a careful examination into the water-supplies of the various municipalities.

At Akola, where the water is derived from infiltration galleries at Kapsi, ten miles from the town, the water fell so low in the upper gallery that it was necessary to pump water from the lower gallery for the supply of the town. A chemical examination of specimens of the supply taken at the gallery and from a stand-post in the town, shewed that the water was of fair quality, and that in its passage along the closed pipes the water had gained slightly in total solids and chlorine, while it had lost free ammonia.

Amraoti camp is supplied with water from a tank at Wadali, the water being derived from an unpolluted catchment area. There are two filter beds, passage through which appears to greatly improve the potable quality of the water. There is a considerable village near the tank ; this Dr. Little considers a source of danger and has recommended its removal.

Amraoti City is supplied from a tank fed from a conserved catchment area in the Amraoti hills. The water is supplied without filtration. Specimens of water taken from the tank and from a stand-post shewed that the water, during its passage through the pipes, gained considerably in total solids, while the free and albuminoid ammonias were considerably diminished.

Khamgaon derives its supply from the Januna tank, about two miles from the town. The catchment area is about 800 acres in extent and is unpolluted. Examination of the water shewed a considerable amount of organic impurity, believed, in the absence of chlorine, to be vegetable in origin.

Buldana obtains water from the Sutrabur tank, situated in a depression between low hills, about a mile from the town. The catchment area is chiefly grass land, but there are teak trees near the tank, and the large leaves find their way into the water. In this

case, although the water in the stand-post was slightly better than that in the reservoir, there was present a considerable amount of organic impurity of vegetable origin.

Only one of the water-supplies, that of Amraoti Camp, appears to be filtered before delivery ; most contain a considerable amount of sediment and organic impurity, and would no doubt be improved by the use of settling-tanks and filter-beds. But these improvements are perhaps, for the present, beyond the means of the communities concerned ; meanwhile the specimens of water at the time they were examined were probably less pure than in a year of normal rainfall ; and care is taken at the sources to prevent the ingress of dangerous impurities.

The street and house-sweepings are sold in most municipalities. In Basim the sweepings are stored in pits, which is said to greatly improve their manurial value. In most of the towns, the nightsoil is trenched or converted into poudrette, but the trenches are not cropped in all cases. The Sanitary Commissioner urges on Municipal Committees the importance of a proper disposal of town-refuse and nightsoil :

" The disposal of nightsoil and sweepings, if efficiently and diligently carried out, must result in " the satisfactory cleanliness of our towns apart from the money income it would bring, and I would " earnestly ask municipal bodies to give this matter a foremost place in their deliberations and work."

A sum of Rs. 1,06,834 was allotted by District Boards for sanitary works and Rs. 82,695, or 77·4 per cent. of the total was spent ; Rs. 28,850 on water-supply, Rs. 12,690 on drainage, and Rs. 37,217 on " domestic cleansing,"—mainly conservancy.

The District Sanitary Boards met six times during the year, once in each district. They considered the measures taken by local bodies to give effect to the recommendations of the provincial Sanitary Commissioner, and recorded their suggestion against each incomplete work. "One tangible result of this action is that, in 1896, a sum of Rs. 51,368 was spent " on sanitary improvements recommended in the Sanitary Surveys."

Proposals to legalise a system of village sanitation were circulated throughout the province, in order to elicit expressions of native opinion. In all, about seventy persons gave their opinions, and were unanimously opposed to any present legislative interference with the customs of the people, in connection with sanitary reform.

Excluding the presidency town, the total income of the remaining 58 municipalities in Madras, was estimated to amount, in 1896–97, to Rs. 33,25,370. The sum allotted to sanitary works was Rs. 16,00,203, or 48·1 per cent. of the total income, and the amount actually spent in the nine months ending with December 1896, was Rs. 9,72,097, including Rs. 2,91,747—little more than half the allotment, on water-supply ; Rs. 4,18,292 on conservancy ; and Rs. 1,93,958 on the improvement of sites. The municipal income of Madras City was Rs. 14,38,560, from which a sum of Rs. 4,48,826 was set aside for sanitation, and Rs. 3,58,466 were actually spent during the nine months, chiefly on conservancy on which Rs. 2,54,343 was expended, against only Rs. 2,976 on the improvement of water-supply.

The Sanitary Commissioner chronicles a noteworthy advance in the views of the majority of the Municipal Councils in Madras. Until recently they were content to provide means to get rid of sewage ; now, it appears, that more municipalities have signified their willingness to undertake public water-supply schemes than the Government are able to provide with grants-in-aid, and engineers. Meanwhile, however, in those towns where public supplies have been provided the old sources co-exist with the new. In this connection certain observations made by Dr. King are important and interesting.

" For example, in Madras in a native house of a respectable, but not wealthy, class having a public " water-tap within 10 yards of it, the supply per head was found to be eleven gallons from a well " in the premises, and 2·20 gallons from the public supply on observation carefully conducted and " extending over a period of ten days : in another instance where only the public supply was used, " the consumption was found to be 14·61 gallons per head—the experiment also extending over ten " days. Again, in such water works as have been formed in the mofussil, the works themselves do " not offer the facilities, nor have the municipalities the apparatus, nor, at present, the wish to largely " use the supply for municipal purposes. With the object of throwing some light on this important " and strictly sanitary question, I circulated to District Sanitary Officers forms asking for measure- " ments of the water-supply of households for seven-day periods, under the superintendence of " medical subordinates. For facilitating calculations an arithmetical table, and forms setting forth the " various domestic purposes to which water is put, were supplied. Altogether the results of 65 " observations extending over the required period were received. The total average shewed that the " amount required for domestic consumption, under the ordinary conditions of native life, was " 16·9 gallons per head per day. This represented water drawn in all instances by manual labour and " carried over varying distances, and it certainly would result, as experience elsewhere has shewn, " that when these difficulties were removed a large increase would be required."

During the year, water-supply works were completed and opened at Trichinopoly and and Dindigul; similar works were in progress in Conjeeveram and Kurnool; and schemes for Negapatam and Conoor were being prepared.

It seems that the water-supply works actually in use are not in all cases quite satisfactory, a state of affairs due, apparently, to defective supervision on the part of the Municipal authorities. The following paragraph quoted from the report of the Sanitary Engineer touches on this matter :—

"The works in operation at Adoni, Cuddapah, Madura and Tanjore were maintained in charge of "the Council throughout the year. Those at Dindigul were handed over to the Council in "September 1896, and those at Trichinopoly in October 1896.

"The following were visited during the year by the Sanitary Engineer, viz., Cuddapah, Dindigul, "Tanjore, and Trichinopoly, and Adoni by the Assistant Sanitary Engineer.

"It cannot be said that the result of the maintenance by the Council is altogether satisfactory. In "the first place there is no professional knowledge on the part of the Chairmen, and they naturally "look with suspicion on requests, the necessity for which they do not understand, feeling themselves "more or less at the mercy of the engine-drivers and overseers in charge. Fuel stock in some places "has been allowed to go much too low, and there is, in certain towns, a tendency to unduly reduce fuel "consumption to save money. The proper class of oil has not always been supplied when required. "Leave has not always been obtainable by the engine drivers, except under conditions which did not "allow of them availing themselves of it. At Adoni the overseer was removed to other duty, "and the water delivered to the town was almost undrinkable in consequence of the wrong working "of the filters.

"There was no detailed inspection of engine and boilers, as the Boiler Inspector was not appointed "during the year."

A scheme for sewering Madras received the sanction of Government, and preliminaries regarding the erection of incinerators for the disposal of rubbish have been settled. Considerable progress was made in the preparation of a drainage scheme for Cuddapah. Pending the introduction of drainage schemes into the municipal towns, efforts are being made by the Sanitary Commissioner to improve and extend existing methods of sewage disposal, and he appears to have achieved a considerable measure of success in certain of the towns. The total sum realized by Municipal Councils for the sale of nightsoil and town rubbish, which in 1895 was Rs. 24,755, rose to Rs. 28,484.

The movement inaugurated in 1894, on the advice of Dr. King, to obtain properly taught sanitary inspectors is progressing favourably. Fifty-two men obtained certificates in 1896; and the entertainment of at least one trained man has been made compulsory in each municipality. Twenty-eight Councils employ certificated Sanitary Inspectors. Four are employed by District Boards, and provision has been made in the budget for 1897–98 for the entertainment of five others. Meanwhile well educated men are coming forward for the special course of instruction.

The total estimated income of the District Boards in 1896–97 was Rs. 79,67,830, of which 8·4 per cent. was allotted to sanitary works, which shews a falling off, as compared with 1895–96, when 9·2 per cent. of the slightly higher total income was set aside for sanitary purposes. The decrease is due to curtailment of expenditure under the heads of education, medical relief and sanitation in favour of the upkeep of improved communications. The expenditure on education is said to be more or less fixed, so that sanitation goes to the wall. On the other hand, the more judicious expenditure of the funds provided for conservancy has been ensured, and the tendency of unions to regard the fitting up of lamps as the most important call upon their income successfully curbed.

The Sanitary Board was reconstituted during the year, and now consists of three members and a secretary—

President.—The Chief Engineer and Secretary to Government in the Department Public Works.

Members.— { The Surgeon-General with the Government.
A member of the Civil Service.

Secretary.—The Chief Assistant to the Chief Engineer.

The Sanitary Commissioner and the Sanitary Engineer are no longer members of the Board and are restricted to purely executive professional work. It is provided that no sanitary work estimated to cost more than Rs. 200, exclusive of the cost of site, shall be undertaken without the previous sanction of the Board.

During the year, the Board scrutinised plans and estimates for 72 municipal, and 87 local fund, works estimated to cost in the aggregate Rs. 2,75,331.

The total sum expended on original works in the municipalities in Coorg in 1896 was Rs. 4,935, the greater part of which was spent on a new lying-in hospital and drains in Mercara, and on the construction of a tank in Somvarpet.

The Department of Public Works also constructed a new well and improved and repaired others at a total cost of Rs. 432. The only scheme of importance in contemplation is that for the water-supply of Virajendrapet, for which a sum of Rs. 500 was placed at the disposal of the Executive Engineer to meet the cost of a preliminary survey.

The Board met four times, and, among other matters, considered :—

(1) Rules for the better sanitation of Coorg. It was resolved that rules should be framed, and submitted to the Local Government for sanction. It will not, it is stated, be possible to introduce such rules into all villages, as there are comparatively few of the sweeper caste in the province.

(2) A rough estimate for the water-supply works of Virajendrapet was submitted by the Executive Engineer. The sum of Rs. 75,610 was considered beyond the means of the municipality, and it was resolved to ascertain whether the amount could not be reduced to Rs. 50,000.

(3) The erection of coolie shelters on the Ghats. The President informed the members that Rs. 2,400 had been collected, that Rs. 600 more were expected, and that Government had sanctioned the grant of a sum equivalent to that collected, besides supplying the necessary timber free of cost. The selection of sites was decided, and it was hoped that the shelters would be ready for occupation before the bursting of the monsoon of 1897.

Excluding the presidency town, the total income in 1895–96 of the 168 municipal towns in Bombay was Rs. 55,22,074, against Rs. 47,49,303 in the previous year. A sum of Rs. 25,01,157, equal to 45·29 per cent., was allotted to sanitary works. As in 1894–95, the expenditure under every head was less than the allotment, but the actual sums spent were considerably larger than in that year ;—on water-supply, Rs. 6,47,329, against Rs. 4,96,543 ; on conservancy, Rs. 11,06,662, against Rs. 8,69,219 ; and on improvement of town sites, Rs. 2,22,905, against Rs. 2,15,979. The income of the District Boards was Rs. 40,05,823. Although the income was higher, the allotment for sanitation was less than in 1894-95, and the whole allotment was not spent. The sum assigned to sanitary works was Rs. 6,85,851, and only Rs. 4,71,536 were spent, chiefly upon the improvement of water-supplies, which absorbed Rs. 4,27,758.

The Bombay Village Sanitation Act has been introduced into every district, except Kanara and Upper Sind Frontier, and is now in force in 222 villages, including 59 in which it was brought into force in 1896. No new sanitary work of capital importance was begun during the year, and progress, generally, seems to have been retarded, chiefly on account of famine, but partly on account of the apathy or obstruction of Municipal Councils.

Progress was made with the water-supply works at Yeola, Surat and Ahmednagar, and improvements were carried out at Hyderabad. A survey of the town of Belgaum was made by an engineer employed by the municipality, and a water-supply project is being prepared by him under the advice of the Sanitary Board. Water-supply projects for Akalkot, Nasik, Viramgam, Hubli, Gadag, Dohad and Dakor were under consideration. Estimates for surveying the town of Sholapur, and the preparation of a plan and estimate for a drainage scheme for the western portion of the town, were sanctioned by Government. A drainage scheme for Sukkur was completed, but it was shelved by the Municipal Council. Drainage schemes for Hubli and Gadag were under discussion.

The number of meetings of the Sanitary Board is not mentioned, but they seem to have done a great deal of useful work during the year. Among other matters they advised regarding the water-supply of Surat and Rander, Malegaon and Islampur, and furnished a report on the water-supply works of Satara.

At Satara the filters may possibly be insufficient, but they are not properly worked, the means of distribution is very faulty and even dangerous, and there is no check on the expenditure incurred. The supervision of the works, it appears, is altogether inefficient, and the water supplied was reported unfit for drinking, whenever it was analysed, except in August. The Board advised the proper completion of the distribution system, the construction of filter-beds and a pure-water reservoir, and the delegation of the supervision of the Kos tank and supply channel to the Executive Engineer.

Regarding the attitude of Municipal Councils the Board write as follows :—

"Finally we would urge that Government should, from time to time, recognise, in some substantial "manner, by suitable titles of honour, any special exertions made by a prominent member of a muni- "cipality in pushing on water-supply and drainage schemes. Owing to the conservatism of natives, "to their great objection to direct taxation, and to the tendency of the Municipal Commissioners, "generally, to subordinate public to private interests, the position of any Commissioner who takes up "sanitary improvement is a thankless and laborious one ; and yet, without some one taking up the

" matter seriously, and pressing it continuously for a long time, it is hopeless to expect any munici-
" pality to overcome its own *vis inertia*. Where there is a question of a municipal appointment which
" might be got for a friend or relation, or where there is a possibility of appropriating municipal funds
" for a school, or something of that sort, every Commissioner will attend; but when it is a matter of
" public health, or sanitary improvements, even a quorum can seldom be got, unless it is a question of
" taxation, when again there will be a full meeting to *oppose* it. There are probably not half a dozen
" non-official Municipal Commissioners in the Presidency who have seriously taken up this
" unprofitable and almost hopeless task; and unless their exertions are in some way recognised, and
" influentially supported, it is only to be expected that they will fall off; and those Commissioners
" who might possibly in time be influenced by these exertions, will prefer to cast in their lot with
" the popular *rôle* of passive obstruction to sanitation, varied by occasional theoretic discussions."

The aggregate income of the various district and municipal funds in Burma, in 1896, was Rs. 71,10,986, of which Rs. 24,59,584, or nearly 35 per cent., was devoted to sanitary works of one kind or another, distributed as follows: to water-supply, Rs. 5,53,609; to conservancy, Rs. 5,74,335; to drainage. Rs. 3,60,505; and to "other " sanitary works," Rs. 9,71,135.

No new work of any magnitude has been undertaken and the following notes regarding the chief towns refer to work in progress rather than to new projects.

In Rangoon, the water-supply continues to occupy attention. The existing supply, although sufficient for present requirements in years of ample rainfall, is of bad quality, and is liable, not only to extensive vegetable pollution, but, as the number of people living on the catchment area is increasing, to contamination of a more dangerous kind; and should the rainfall be deficient, there would be serious scarcity. Deep borings have shewn that supplies from subterranean sources, at a depth of 200 to 300 feet, are ample in quantity, and in some cases, of good quality; but, so far, experiments conducted under the supervision of an expert from England, have not proved successful, and, of the various other schemes for increasing the supply that have been suggested, the most feasible is said to be the construction of a new lake in the neighbourhood of Thameing.

Sewage is removed on the Shone and Ault system, and most of the houses in the town are now connected; while, in the suburbs, the contents of latrines are removed to depôts connected with the sewers. Regarding the efficiency of the system, the following remarks, taken from the report on the working of the Rangoon Municipality, are of general interest:—

" Both the Municipal Engineer and the Health Officer report favourably on the Shone system of
" sewerage. The system is fully adopted in the *town* between Judah Ezekiel Street and Godwin
" Road; in Lanmadaw sewers have been laid, but house connections are not insisted upon,
" therefore only a partial benefit is derived. In the *town* east of Godwin Road there are 2,724 house
" connections and, consequently, the system is thoroughly efficient. No blockages of any kind occurred
" in the mains, and it is not thought at all likely that any blockage will ever occur in them. The
" engines and air-compressors have also given complete satisfaction: the addition of plummer blocks
" outside each fly-wheel has added to the efficiency of the engines, as they have enabled them to be
" worked more steadily and at a higher rate of speed.

" During the year 624,048,000 gallons of sewage were ejected at a cost of 1 anna 8·5 pies per 1,000
" gallons, which is a moderate rate. The Shone system in Rangoon has now been worked for years:
" it has stood the test of time and has withstood criticism both interested and disinterested. Its
" benefit to Rangoon is incalculable and can only be appreciated by those who lived in the *town* prior
" to 1890, and had to submit to the foul nuisances which then abounded in every street, and who had
" in the hottest night to keep every window closed or allow their houses to be rendered almost
" uninhabitable by the awful stench from passing night carts. The Committee of 1886, with a much
" smaller revenue than is now available, shewed considerable courage in embarking upon an
" expenditure of 30 lakhs for a drainage scheme on a system, which, until then, had not been tried on
" so large a scale, but the result has been a complete justification of the course the Committee then
" took, and the inhabitants of Rangoon owe a debt of gratitude to those who, in spite of considerable
" opposition, gave Rangoon a drainage scheme on a system that by its satisfactory working has proved
" a complete boon."

The reclamation, on a great scale, of low swampy lands on the east of the town continues in progress.

In Moulmein, a report on a water-supply scheme was considered by the Municipal Committee, but, although it was generally approved, some details require remodelling, and the loan of the services of an officer to do this has been asked from the Local Government.

At Prome, the filter-gallery connected with the pumping-station got out of order, and the Superintending Engineer of the Irrigation Department inspected it, in order to ascertain what alteration is required. In the meantime, water was taken direct from the river through a strainer, at a point which was considered by the Health Officer to be too near the bank.

At Bassein the question of a general water-supply is engaging attention. Experimental borings have been made, and water obtained from a depth of 280 feet, but not of good

quality. The night conservancy scheme has been extended, and no cess-pits now exist within the limits served, except those on the banks of creeks. The contents of 535 public and private latrines are removed daily in covered buckets and air-tight conservancy boxes, on tram trucks, to Pandingôn, situated about half a mile from the town, and there trenched.

At Mandalay, no water-supply scheme has, as yet, been undertaken. Experimental wells sunk in an old bed of the Irrawaddy to the north of the city yielded very hard water, and a scheme, to obtain water from the river near Amarapoora, is now being considered. The objection to this scheme is the liability to pollution from surface drainage of the town—a liability which will increase as drainage improves.

Except in remote districts, village sanitary inspection registers have been introduced, and after certain modifications in the form of the registers, shewn by experience to be requisite, have been made, good results of their use may be expected.

The Sanitary Board met once during the year and, with reference to a communication from the Local Government, made at the instance of the Government of India, resolved that, as eleven of the towns in the province were provided with complete maps, the time had come to appoint a Sanitary Engineer.

APPENDIX A.

RESOLUTION.

SANITATION DEPARTMENT.—*Dated Naini Tal, the 14th September*, 1896.

READ—

(1) Resolution No. $\frac{27}{V-10B.}$, dated 9th February 1889, in the Sanitation Department.

(2) Resolution No. $\frac{42}{V-10B.}$, dated 6th March 1890, in the Sanitation Department.

(3) Resolution No. $\frac{561}{V-10B.}$, dated 21st December 1893, in the Sanitation Department.

OBSERVATIONS.—In the first of the Resolutions read in the preamble, the Government of these provinces explained the manner in which it proposed to give effect to the wish of the Government of India that for the furtherance of sanitary reform and for the guidance of local executive agencies in urban and rural areas a Sanitary Board should be appointed in each province, which should supervise and control all sanitary works in progress or projected; should initiate and direct the sanitary survey of each municipal and rural area; and should devise such simple rules for the improvement of village sanitation as experience might shew to be necessary and practicable. The Sanitary Board established in these provinces by the Local Government, in pursuance of this policy, was tentatively constituted as a consultative and not as an executive agency. It was charged with the duty of instituting a sanitary survey of the province, and especially of ascertaining the localities in which the presence of canals or railway systems made large schemes of drainage necessary. It was required to report on the best methods of introducing sanitary reforms in rural areas; and it was made the referee and adviser of Government on all questions specially remitted to it for opinion by the Government, the Sanitary Commissioner, or Commissioners of Divisions.

2. The Board thus constituted has done useful work. It has assisted the Government in improving the provincial system of mortuary and birth registration. It has reported from time to time on the drainage requirements of the country. It prepared the first draft of a village sanitation Bill which eventually was enacted by the Provincial Legislative Council, and it framed the rules by which effect is given to the Act. This Act marks the first stage in the improvement of the sanitary condition of rural areas. But it is as yet in force in only eight districts, and even in those districts it can be applied only to villages with a population of 2,000 and upwards. The general problem of rural sanitation is scarcely touched by it, and the preliminary measure of a detailed sanitary survey of each district has not even been commenced. The time has come, in the Lieutenant-Governor's opinion, for a fresh advance on the lines of the policy laid down by the Government of India in its Resolution of 27th July 1888. His Honour has therefore decided to strengthen the Provincial Sanitary Board, and to increase its powers; and he proposes to create, as time goes on and funds become available, an efficient sanitary agency in each district, to co-operate with the Sanitary Board.

3. With regard to the Sanitary Board, the following rules, which will take effect from the 1st November next, will regulate its constitution, procedure, and powers:—

I.—The Sanitary Board of the North-Western Provinces and Oudh shall consist of the following permanent members, of which three shall form a quorum:—

(1) The Inspector-General of Civil Hospitals ... ... *President.*

(2) One of the two Secretaries in the Department of Public Works as the Lieutenant-Governor may from time to time nominate.

(3) The Sanitary Commissioner.

(4) The Sanitary Engineer ... ... *Secretary.*

II.—The Board, in addition to such meetings as may be needed for the despatch of ordinary business, shall sit once a year in each revenue division, and, when sitting in a division, shall have as additional members—

(*a*) Commissioner of the Division.

(*b*) The District Magistrate ... ... }
The Civil Surgeon ... ... } of the district whose sanitary business
The District Engineer ... ... } is being considered at the time.
A delegate from the District Board ... ... }

When the sanitary business of a municipality is under consideration, a delegate from the Municipal Board and the Municipal Engineer (if any) shall take the place of the District Board's delegate and the District Engineer.

III.—The Board shall keep minutes of their proceedings, and these will form the basis of a chapter in the Sanitary Commissioner's Annual Report.

IV.—At the commencement of each year the permanent section of the Board shall draw up a programme for the year, fixing the dates and places of meeting, and notifying any important subjects which may be for consideration in each division. It will not be possible to notify beforehand the detailed proposals which district authorities may have to bring forward. References from Government in local sanitary matters will be considered at these meetings, and plans adopted.

V.—Under rules about to be issued to define the procedure of Municipal Boards with regard to the preparation and execution of public works projects, the Sanitary Board will be the adviser of the Commissioner of the Division as to whether administrative sanction should be given or withheld when projects of a sanitary character are submitted to him for sanction. With regard to sanitary works undertaken by District Boards, the Sanitary Board will give administrative sanction to all works towards the cost of which it may contribute from funds placed by Government at its disposal for this purpose. It will also advise the Commissioner of the Division as to giving or withholding administrative sanction to all other projects of a sanitary nature proposed to be executed out of the District Board funds alone when the estimated cost exceeds Rs. 1,000 and does not exceed Rs. 10,000.

These rules, it is hoped, will bring the Sanitary Board into close relations with the district administration, and enable it to supervise and guide the general progress of rural sanitary reform.

The next step is to lay down the lines on which the executive sanitary agency in each district should work. As regards this agency, the chief sanitary officer of each district will be, as he is at present, the Civil Surgeon. He has now at his disposal the subordinate staff of the Vaccination Department from the Assistant Superintendent downwards, and he may utilize their services for sanitary work throughout the district so far as their vaccination duties and their qualifications permit. But it must be admitted that the subordinate staff of the Vaccination department at present know little or nothing of sanitation, and that in this regard small help can be expected from it. If sanitary progress is to be made in rural villages, the *personnel* of the staff must be improved. Measures are contemplated which will strengthen this staff and make it more competent for the combined work of vaccination and rural sanitation. In the larger districts, where the duties of the Civil Surgeon are heavy and multifarious, it is proposed at once to give him the services of an Assistant Surgeon as Sanitary Assistant, and the intention is eventually to post such an officer to each district. Financial reasons may for some time compel the Civil Surgeons of the smaller districts to dispense with this special assistance, but it is thought that without it some progress may be made in the preliminary work of a detailed sanitary survey of rural areas, with the co-operation of the revenue district staff under the orders of the Collector. In view of the increased attention which under such a survey mortuary and birth registration will require, it may be necessary to give the Civil Surgeon more clerical assistance in this branch than he has at present. The Sanitary Board will be consulted on this point.

5. The first step in the sanitary survey of a district is to group the villages, for purposes of detailed and continuous observation, into smaller registration areas than the present *thana* circles. The sub-circles thus to be formed in each existing rural circle are intended exclusively for district sanitary work; for all statistics returned to the Sanitary Commissioner the *thana* circle will remain the unit. In forming the sub-circles the following rules should be observed :—

(1) Municipalities, cantonments, and Act XX. towns will be excluded, as they already form separate units.
(2) A sub-circle should, if this be possible consistently with the provisions of rule (4), contain not less than 10,000 and not more than 15,000 inhabitants, the lower limit being suitable for sparsely inhabited and the higher for populous tracts.
(3) A sub-circle should be compact and, so far as possible, homogeneous in physical and hygienic character.
(4) A sub-circle shall not extend into two *thánas*.
(5) A sub-circle, so far as is compatible with the preceding rules, should include entire *patwári* circles.
(6) The sub-circles should be numbered, a single series of numbers for the whole district being used.

6. The Civil Surgeon, in blocking out these sub-circles, should consult the Collector, who, in giving the requisite assistance, will utilize the local knowledge of tahsildars and kanungos and other members of the district staff. The object to be aimed at is to so group the villages of each *thána* that the grouped villages may present fairly like conditions of health, and the group represent a real unit. The mortuary and birth returns of groups so formed will have an import in connection with the localization of disease and insanitary conditions which those of existing *thána* circles cannot have, and the intelligent study of these returns by the Civil Surgeon and his Sanitary Assistant will be the first step in the direction of systematic sanitary reform in rural areas. An effort should be made to have the sub-circles blocked out and numbered in each district before the 31st December next, so that from the 1st January 1897 births and deaths in each *thána* may be recorded in separate registers for each sub-circle, and separately returned month by month for each sub-circle to the District Registrar. The Sanitary Commissioner will be asked to frame such subsidiary instructions as may be necessary for the guidance of circle registration officers. He will also be asked to say whether it would be possible to compile from the *thána* registers mortuary and birth statistics for each group for each of the past five years, so as to at once give the Civil Surgeon, as chief sanitary officer of the district, a basis of fact from which to work.

7. The investigation of the sanitary condition of each circle will follow. In districts to which it is found possible to attach a Sanitary Assistant to the Civil Surgeon, he will be employed by the latter as his chief inspecting officer. In these and other districts the Civil Surgeon will also utilize the Assistant Superintendent of Vaccination and his subordinates, and will have the assistance of the district staff, and all reports by the members of the staff on the sanitary condition of villages will be sent to him by the District Magistrate to be collated and recorded in a permanent register. It will be his duty to bring all these reports to a focus, and to work them up into a shape in which they may be submitted to the Sanitary Board. When worked up, the reports should be very brief and more in the form of notes on the various villages, under heads to be prescribed by the Board, than of descriptive narratives. For preparing these reports the Civil Surgeon may, as has been already remarked, require more clerical assistance than he has at present. An Assistant Magistrate in training, or other available member of the district gazetted staff, may be very usefully employed in aiding the Civil Surgeon in this connection.

8. The sanitary improvements which this investigation into the condition of rural areas may suggest will fall into two classes. The first class are those which concern the construction or repair of wells and tanks for drinking water and the drainage of the village site, and which require some expenditure of money. The second are those which merely involve the observance of simple sanitary rules or the exercise of a little energy on the part of owners and occupiers of the village. The funds for the first class of improvements will be provided by the District Board ; by grants-in-aid from the Sanitary Board within the limits of the sum which Government may be able annually to assign to that body ; by moneys leviable under the Village Sanitation Act ; and by local contributions. The amount which a District Board can spare from its funds for rural sanitation may not, to begin with, be large; but some provision, however small, should, in future, under the proposed scheme of local finance, be made for this purpose in every District Board budget. The Local Government will, when the state of the finances permits, make an annual grant-in-aid of rural sanitation ; and the Lieutenant-Governor and Chief Commissioner hopes that public liberality will also assist to the same end.

9. As regards the second class of improvements, which may generally be described as connected with the preservation of the village water-supply from pollution and the village site from being befouled, these require nothing more than the observance of simple sanitary rules by the village community. Again, the filling up of pits and stagnant pools within the village site, the clearance of jungle from it, and the execution of simple repairs to wells and tanks by the persons owning or using them, require only the contribution of a little assistance in materials and labour, or the expenditure of a little labour which hurts no one, and will, if the matter is gone about in the proper way, be willingly given. The appointment of places for the deposit of manure and household refuse, the regulation of burials and of the practice of offensive trades—these and similar matters will in due time, when village opinion is ripe, be brought to the notice of the village *panchayat*. At present the law does not empower the District Magistrate, except in the comparatively few villages to which the Village Sanitation Act has been extended, to enforce rules on these points. But much has been, and is being, done in many districts by persuasive executive action to introduce and render sanitary rules effective, and what the Lieutenant-Governor desires is that, pending the amendment of the law in this respect (should amendment eventually be found desirable), the District Magistrate and the District Board will co-operate with the Chief Sanitary Officer of the district in extending the observance in villages of simple sanitary rules, of proved utility. It will be open to the Provincial Sanitary Board to examine such rules and to suggest such improvements as experience may dictate. But here it may be said, for the Board's general guidance, that they should discourage rules and works which are not of a simple character. No attempt should be made to introduce the latrine system, and what is done, or attempted to be done, should be unpretentious, agreeable to the feelings and wishes of the people, and in general harmony with existing village practice.

10. The promotion of sanitation in municipalities will be equally within the functions of the Sanitary Board, and at its meetings the wants of municipal areas will be considered no less than of rural areas. But as municipal funds are fairly adequate to town wants, while the supply of money of rural sanitation must for many years fall short of the demand, no contribution should be made in aid of municipal resources from the funds placed at the Sanitary Board's disposal.

General Remarks.

Red Sea Pilgrim Traffic.—The following short summary of the main facts regarding the Red Sea pilgrim traffic in 1896 is taken principally from the Report forwarded by the Health Officer of the Port of Bombay.

During the year there left Bombay for Jeddah, nineteen steam vessels of the usual class which provided accommodation, on the scale laid down by the Native Passenger Ships Act, for 14,478 adults. The total number of pilgrims who left Bombay, excluding 311 passengers for intermediate ports, was 14,167, comprising 13,230 adults, 764 children between one year and twelve years of age, and 173 infants. The average duration of the voyage, excluding detention at Camaran, was 14 days. The total number of pilgrims who were admitted to hospital while at sea was 271, and of these 49 died, including 18 whose deaths were ascribed to general debility, 3 of old age, 2 of small-pox, and 1 of choleraic diarrhœa.

The new Pilgrim Ship Act of 1895 was brought into force from the 6th of October 1896. This Act, among other provisions, requires that each pilgrim shall have six feet square of free space upon the upper deck, in addition to either 12 square feet on the 'tween decks, or 16 square feet on the orlop deck. To ensure thorough ventilation, it is

also required that, besides hatches and scuttles, each pilgrim on the 'tween decks shall be provided with 5 square inches of ventilating opening and each pilgrim on the orlop deck with 10 square inches. Five vessels left after the new Act came into force, but no pilgrims were carried on the orlop decks.

The medical inspection of the pilgrims was carried out as usual, valuable assistance being rendered, especially after the new Act came into force, when the inspections were more tedious and complicated, by the officials of the Preventive and Police services.

The quarantine station at Camaran was opened on the 18th December 1895, and the usual quarantine of ten days was imposed on all pilgrim-ships arriving just prior to the Haj, which took place on the 23rd of May.

On the return voyage to Bombay there were engaged nineteen vessels providing accommodation, under the law, for 15,222 adult pilgrims. At Jeddah 11,133 pilgrims embarked, and at Camaran 63. At Aden and Karachi 1,363 pilgrims disembarked, and 9,697 were landed at Bombay.

As usual, the homeward voyages were much the more unhealthy. There were 365 admissions among the returning pilgrims and 136 deaths, including 34 from debility, 21 from senile decay, 19 from choleraic diarrhœa—against only one in the outward voyages—and 14 from chronic dysentery.

In 1896 the difference between the total number who went to the Hejaz and the numbers that returned was only 15 per cent., against 28 per cent. in 1895, and an average in former years of about 33 per cent.

No vessel left either Calcutta or Madras for the Hejaz, but the S.S. *Sultan* arrived in Calcutta from Jeddah on the 23rd of June. She had on board 1,112 pilgrims, and there had been 44 deaths during the voyage, including 13 from diarrhœa, 11 from lung diseases, and 7 from small-pox.

Researches by the Special Assistant.—During the latter part of the year 1896 and the first few months of 1897, the work which was done in the laboratory attached to the office of the Sanitary Commissioner was mainly devoted to investigations into the question of the alleged occurrence of plague in Calcutta, and to the continued elucidation of certain points in connection with the physiological action of snake venom and the nature of the artificial immunity from which is established under the influence of continued and cumulative introduction of the toxin into the animal organism.

Shortly after the existence of plague had been recognised in Bombay, it came to be currently believed that cases of the disease had been detected in Calcutta among both the civil and the military population. The observers who were primarily responsible for the origin of this belief did not affirm that they had any satisfactory clinical evidence for it, and founded their diagnoses solely on the results of microscopical examinations and cultivations of specimens of blood derived from the bodies of the suspected patients. The matter was one which, from its important bearing on mercantile interests, could not be allowed to remain undecided, and a careful investigation into the nature and value of the bacteriological evidence which had been adduced in regard to it was accordingly undertaken.

A series of type specimens of blood and hæmatic cultivations from suspected cases was accordingly procured and submitted to careful examination and comparison with specimens and cultivations prepared in the laboratory, and the data which were thus obtained were of a nature which appeared clearly to justify the conclusion that the bacteriological evidence which had been brought forward in support of the alleged prevalence of plague was entirely insufficient and fallacious. The grounds for this conclusion were the following :—

1. The schizomycete organisms which were present in the type specimens of blood were not invariably of the same nature.
2. In many instances they presented no morphological resemblance whatever to typical plague bacilli ; in some they were unequivocally mere accidental contaminations of aerial origin ; and, in others, what had been regarded as schizomycete organisms were apparently mere products of nucleoplastic disintegration.
3. The growth in the various type cultivations were not of any uniform character, and some cultivations contained growths of more than one kind of organism.
4. Specimens of blood taken under proper precautions from certain of the alleged cases of plague showed no evidence whatever of the presence of any intrusive schizomycetes, and corresponding cultivations entirely failed to yield any growths.

5. A very brief exposure of the blood of perfectly healthy animals to free contact with the air of the laboratory was sufficient to secure the subsequent appearance in them of a number of distinct forms of schizomycetes, some of which were absolutely identical in characters with those present in the type-specimens of blood and the type cultivations derived from the alleged cases of plague.

Full details in regard to the results of the experiments dealing with snake venom will appear in a forthcoming number of "Scientific Memoirs by Medical Officers of the "Army of India," and, in the meantime, it may be sufficient to mention that they conclusively demonstrated that the artificial immunity attending repeated and cumulative injections of venom persists unimpaired throughout periods of many months' duration, and afforded additional evidence in support of the view that the phenomena attending intoxication by cobra-venom are primarily dependent on the occurrence of important changes in the constitution of the blood, and not on any direct action of a toxin upon the nervous apparatus.

LIBRARY OF THE BOMBAY BRANCH OF THE ROYAL ASIATIC SOCIETY

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1896.

(Surgeon Lieutenant-Colonel W. G. King.)

General Population.

Vital Statistics.

The population for which birth and death registration returns were received in this office during the year amounted, according to the census, to 32,761,209—or 91·9 per cent. of the total of 35,641,828 ascertained on last census. Allowing for the intercensal rate of increase, the population under registration amounted to 36,656,033 on the 31st December 1896. Taking the net result of emigration and immigration statistics for the year under report, it is found that the Presidency lost 32,833 souls.

System of birth and death registration.—The system of registration of births and deaths in the Madras Presidency continued the same as in 1895, but under Order No. 476, Revenue, dated 21st September 1896, the following changes were sanctioned :—

(1) Candidates for the public service and school boys, who were born in municipal towns in which the compulsory system of registration has been in force for many years, should be required, after a certain date, to produce attested extracts from birth registers.

(2) That the number of Union and Municipal registrars be calculated with reference to the population and area of the municipal towns and unions.

(3) That printed forms [in lieu of existing loose forms] bound into books be supplied to all registrars.

(4) That steps be taken to punish negligence.

(5) That special inducements be offered to all municipal servants for reporting cases of unregistered births or deaths.

In other respects, the system remains as described by me in my report of 1893.

The inspection report forms used by District Medical and Sanitary Officers were revised by me so as to require further attention to the details of registration. Information gathered from these sources, together with that secured by personal inspections by my Deputy and self, was duly forwarded with remarks to the Collectors of the districts concerned, who, in all cases where neglect of duty by Village Heads was proved, took action to prevent a recurrence of omissions. In the month of October 1896, having regard to the approaching scarcity, a special circular letter was forwarded to Collectors advising increased attention to the question of correct registration.

The birth and death rates for the whole Presidency were 29·9 and 20·6 per 1,000 of population respectively, as compared with 29·1 and 19·6 in 1895.

In rural areas 904,112 births were registered: the birth-rate for the Presidency as registered was therefore 29·9 against 29·1 of 1895 and 27·2—the average of the previous five years.

The natural increase of the population of the districts, as a whole, was 35,144,977. Reckoned upon the "estimated population," the birth-rate was 26·7 per 1,000 of the population, or 0·3 per 1,000 less than registered during 1895. A further method of correction is legitimate in attempting to gauge the birth-rate of the Presidency or—to put the matter in more exact terms—the efficiency of registration; namely, by excluding the districts of Ganjám and Vizagapatam, where, on account of large tracts being up to date under the administration of zemindars, the statistics are markedly less reliable than elsewhere. If a calculation be made on this basis, it is found that the birth-rate of the Presidency for 1896 was 30·0 when reckoned upon the Census, and 27·4 upon the "estimated population."

The births of boys were in the proportion of 104·8 to every 100 girls. The months in which the greatest numbers of births occurred were July and August, which allowing for an average interval would indicate the influence of the favourite marriage seasons of Chitrai, Vaikasi and Ani corresponding to the months of April, May, June and July.

There was a decrease of the births in 1896 in 9 and an increase in 12 of a total of 22 districts.

Seeing that it is well recognized that up to date it has not been possible to secure, in tracts of the country where registration is not compulsory, any approach to the normal birth-rate, as proved by the ascertained intercensal rate of increase, it is a matter of

difficulty to decide how far the decrease in 9 districts is due to carelessness in registration, and how far to actual diminution in the number of births. So far as Revenue authorities are concerned, I should feel inclined to believe that the pressure brought to bear upon them by Government has been productive of greater zeal on the part of village heads. The only factor which, it is easily recognised, would have operated adversely, as to zeal in registration, is the steadily decreasing number of rural inspections (under the influence of G.O., No. 57, Public, dated 24th January 1895), effected by District Medical and Sanitary Officers, seeing that, when the rates obtained from areas where registration is compulsory are regarded, there is no evidence forthcoming that the decrease in births has been real ; on the opposite, municipalities, as a whole, shew a decided increase. Against this, however, it might be pleaded that the town and municipal populations, irrespective of age constitution, cannot, in all respects as to vital statistics, be considered fairly comparable. Thus, having regard to the advent of an "evil cycle," in which it is prophesied by Hindus that famine and pestilence will affect the land, it is quite possible that marriages in the rural tracts have been postponed on the advice of astrologers during 1895-96. Again, it was the rural population that suffered chiefly during the famine of 1876–77, and in which, consequently, as the survival of the fittest, the people at child-bearing ages have since been predominant. As shewn by Mr. Stuart, the rate of increase between the Census of 1881 and 1891 was thus beyond what might normally be expected. Taking into account the probable child-bearing period of the Indian, it may now well be that we are entering upon a period when a fall in the rural birth-rate must be expected. But, whilst some influence from these factors may be conceded, it must be held that, if there has been no decrease of activity in registration of births in these districts there has at least been no increase, seeing that between the rate as registered and the actual birth-rate, even if such allowance be made, there is an enormous gap.

In Ganjàm, Vizagapatam and the Nilgiri districts, a considerable improvement in tracts long notorious for slackness in registration has occurred. The advance accomplished by South Arcot is noteworthy, and significant of the interest in matters sanitary, generally taken in this district. On the other hand, Malabar shews even worse results than in former years.

There were 75,869 births registered in municipalities, yielding a ratio of 36·1 per 1,000 of the census population, and 33·2 of the "estimated population," against 35·3 and 32·8, respectively, during 1895. The births of boys were in the proportion of 104·9 to every 100 girls—a very close approximation to the rural rate.

Out of 59 municipalities there was an improvement in 34, and in 23, namely, Anantapur, Adòni, Coimbatore, Karùr, Chicacole, Berhampur, Ellore, Masulipatam, Bezwada, Kurnool, Madras, Dindigul, Palni, Cannanore, Nellore, Vellore, Tìruppattùr, Negapatam, Mannàrgudi, Tinnevelly, Palamcottah, Srìrangam, and Anakapalle there was a falling off.

The following statement exhibits the incidence of death causes in the whole Presidency per 1,000 of population" :—

Years.	Birth-rate per 1,000 of the estimated population.	Death-rate per 1,000 of population.						
		Cholera.	Small-pox.	Fevers.	Dysentery and Diarrhœa.	Injuries.	All other causes.	Total.
1891	27·4	3·5	1·4	7·3	1·0	0·3	9·4	22·2
1892	25·1	2·3	1·3	8·3	1·0	0·3	9·0	22·3
1893	27·0	1.0	0·8	7·7	0·7	0·3	8·8	19·3
1894	27·7	1·3	0·3	8·0	0·7	0·3	9·3	20·0
1895	29·1	0·6	0·1	8·2	0·7	0·3	9·5	19·6
1896	29·9	1·5	0·3	7·9	0·7	0·3	9·8	20·6

The total death-rate was therefore slightly above that of the preceding year, which was the healthiest for a period of eight years. The infantile death-rate was 163·0 per 1,000 of births registered.

In rural areas 611,201 deaths were registered, yielding a ratio of 20·0 per 1,000 on the census, and 17·8 on the "estimated population," against 19·0 and 17·6, respectively, of the year 1895, and 20·0, the average for the previous five years.

During the last quarter, famine conditions prevailed in the Deccan Districts. Labour was, however, promptly supplied by Government. Under the influence of drought, malarial fevers declined. Hence no increase of gross mortality is demonstrable ; but, in certain areas of the affected districts, the death-rate rose with respect to the susceptible ages of from 1 to 4 and above 50 years.

The death-rate in the total municipal towns amounted to 30·7 per 1,000 of the census, and 28·2 per 1,000 of the "estimated population." The increase of mortality beyond that of 1895 occurred chiefly under the head of cholera. In the case of only 15 towns was any decrease of total mortality noted when compared with that of 1895 ; of these, the decrease of death-rate synchronous with increased birth-rate of Cuddapah was most noteworthy. The total infantile mortality was 232·9 per 1,000 of births, against 223·0 of the previous year.

Chief Diseases.

Cholera.

A total of 47,847 persons died of cholera during the year under review, or 1·5 per 1,000 of the estimated population. This was considerably in excess of the incidence of this disease last year, when the rate registered was 0·6 per 1,000. Nevertheless, this heavy mortality compares favourably with that of such recent periods as 1891 and 1892. Certain districts suffered out of all proportion to others. Thus, Bellary, lost a total of 4,205, and Coimbatore 10,731, or 4·7 and 5·4 per 1,000, respectively, of their populations. In Malabar, Bellary, South Arcot and Tanjore cholera was present in each month throughout the year.

The mortality in municipalities from this disease was at the rate of 2·1 per 1,000 of the population, there being a total of 4,371 deaths. The towns of Tiruppattúr and Vániyambádi contributed 556 deaths, yielding a rate on their small populations of 16·2 and 18·2 per 1,000 respectively. In paragraph 46 I have referred to the fact that there is a regrettable tendency on the part of councils to delay taking the necessary steps under G.O., No. 1536 M. of 9th September 1896, with sufficient promptitude for the combating of cholera. Unless councils can be taught to take a pride in being absolutely prompt in appointing the necessary staffs, instead of pursuing the impotent method of saving a few rupees at the commencement of an epidemic whilst waiting till they are *quite sure* cholera has established a firm foothold in their towns, I need not say that, irrespective of the favouring influence of the evil conditions of water-supplies in most of them, loss of human lives from this preventible cause is inevitable.

Small-pox.

With few exceptions, deaths were reported from small-pox in each district in each month of the year. Nevertheless, in only four districts—Anantapur, Ganjám, Kurnool, and North Arcot—did the mortality exceed 0·3 per 1,000 of the population. The total deaths amounted to 8,867 in rural areas. In municipalities the death-rate upon the estimated population from small-pox amounted to 0·2 per 1,000, representing a total of 543 deaths. The incidence of small-pox mortality did not exceed 0·5 per 1,000 in 50 of the total towns. The brunt of the mortality was, however, borne by the towns of Vellore and Gudiyattám, amounting to 5·3 and 2·1 per 1,000 respectively. In the case of Vellore, the Municipal Council must, in great part, be held responsible for the mortality which occurred, as they neglected, in spite of remonstrances, to enforce vaccination, assigning as their reason that they considered this operation inappropriate during the existence of small-pox—a want of action that was duly condemned by Government on my bringing the fact to its notice. In the case of Gudiyáttam from enquiries on the spot, there would seem to have been at first a want of appreciation of the efficacy, and necessity for re-vaccination.

Fevers.

The incidence of fever on the population varies but slightly from year to year. The death-rate of 1896 (8·0) shews a decrease of 0·3 compared with 1895, and we have to go back to 1891 to find an equal decline. Both these years of small fever incidence were, as in the case of 1896, periods of deficient monsoon in the Ceded Districts, where malarial fevers are largely prevalent. In the case of Cuddapah, there were 2,292 deaths less registered from this cause alone.

In municipal towns, a satisfactory decrease occurred in Cuddapah, and a less marked but still appreciable decrease is evident in the case of Madras. In the former, the decrease must be ascribed to conditions common to it and the district—to which I have already alluded ; in the case of Madras, nearer approach to the normal sub-soil water level than

has existed since the exacerbation of malarial fever prevalence attracted attention, namely, in 1890, has, in my opinion, resulted in a decline of the fever rate. On this matter, a special report has, at its request, been submitted to Government. The town of Karúr exhibited a heavy increase of mortality from fever during the year, namely, 16·5 against 10·6 of 1895. In this case the sub-soil of the town is saturated with soakage from cess-pools, and as typhoid is a recognized disease in this town, it need not be assumed that solely malarial fever was dealt with.

Dysentery and diarrhœa.

The death-rate for dysentery and diarrhœa (0·7 per 1,000) shewed little difference in rural areas when contrasted with that found in 1895. Chingleput took the lead with a death-rate from this cause of 2·1 against 1·9 of last year. This district is notorious for bowel affections. This increase may be due to a better rainfall in certain parts of the district than it has had for some years past, bringing about access of water to tanks from more than usually distant parts, and with it filth, that would have been out of range of influence in ordinary years, or to fluctuation of the sub-soil water beyond normal limits. It is probable that much of the so-called dysentery and diarrhœa of South Canara and Malabar is due to catarrhal inflammation of the intestines following exposure to wet, which must form a prominent feature of the every-day life of the labourer in these districts. The rate for municipalities, as a whole, was 3·8 per 1,000 against 0·7 in the case of districts. With the exception of Coonoor, Guntùr, Coimbatore, and Vizianagram, no municipality shewed a marked increase of rate above the preceding year, whilst there were several noteworthy decreases, namely, in the case of Karùr, Chicacole, Rajahmundry, Palni, Tirupati, Mangalore, and Vizagapatam.

Injuries.

A total of 10,822 deaths was recorded from injuries which affords the invariable figure 0·3 per 1,000 of the population—a ratio which demonstrates the well-known fact that the occupations of the population vary but little from year to year, and that consequently the chances of injuries are the same even to subjection to deaths by snake-bite. Not until huge manufacturing or mining enterprises are started in the Madras Presidency is this curiously definite figure likely to vary from year to year. When this occurs, not only will the ratio for injuries alter, but also for suicides, as a result of change of habits and nature of demand upon the nervous system.

Sanitary Works.

Municipalities.

Including Tiruvannàmalai which was formed into a municipality in October 1895, and Chingleput made so in the latter part of the year under report, there were in all 59 municipalities. These embrace a population of 2,153,921, or 6 per cent. of the total population of the Presidency. As the District Boards Act (Act No. V of 1884) is of very little use in respect of sanitary provisions, it may be said that practically the population stated represents the total subjected to constant sanitary discipline. It cannot be said that the rate of sanitary progress in municipalities is such as to render the sanitarian sanguine. Still progress is apparent, and, this being so, it may be assumed that reforms will be introduced in an ever-increasing ratio, as one improvement is almost necessarily followed by another with the object of securing full results. Many legal difficulties that have been rendered apparent in the past, will be swept away by the Amended District Municipalities Act, which will come into force in 1897. Although there are certain municipalities which still remain unpersuaded as to the necessity for action in this respect, as a rule there is no doubt that the sanitary safety and convenience offered by public water-supplies are well appreciated ; indeed, more municipalities have represented their willingness to undertake schemes than Government can supply with grants-in-aid or the requisite engineering staff. This tendency I regard as a noteworthy sign of advance, as it is but a short time back they were well content that reform should commence by getting rid of sewage from the areas under their charge—regardless of grossly insanitary and repugnant forms of water contamination ; in reality not from any just appreciation of the sanitary results that might be expected, but with the object of aiding public comfort. Nevertheless, whilst it is fully understood that the obtaining of Government sanction for water-works will be of benefit to the people—works that are carried out at their expense, but do not depend upon their personal efforts for elaboration—it is extraordinary the apathy with which small measures which in the aggregate would do much to improve the general health of towns, and which are within the power of councils to accomplish, are frequently regarded. This results from the fact that the actions of most councils are trammelled by factions. A suggestion for a sanitary improvement from one of the " Opposition " is liable to be regarded as equivalent

to a vote of confidence in the Chairman and his party, it being a reflection on the sanitary administration of the town : and, if a proposal proceed from the party in power, it is equally likely to fall to the ground, because the Opposition feels it incumbent upon it to protect the pockets of the tax-payers and pose as their protectors from the influence of expensive changes founded upon mere theory. It is only in treating the advice of the Sanitary Commissioner that a really safe neutral ground is obtained : here both parties are not infrequently of opinion that the "least there is said the sooner it will be "mended;" suggestions from this source are very often buried in peace with the superscription "will be attended to." I, however, unfortunately for the peace of the councils, arrange for a resurrection of these proposals at intervals, by seeing that all promises of this description are duly registered in my office ; in the end, even with so unpromising a method of disposal, action is *occasionally* secured.

Acting upon the suggestion as to the backward state of conservancy in municipal towns conveyed in my Report of 1894, paragraph 63, Government called upon the Sanitary Board to draw up schemes for the various towns. As, however, the Board, instead of using the data at its disposal for excogitating schemes that might subsequently have undergone modification, on discussion by the councils, have referred the whole question to the councils without adding, as far as I know, any suggestions as to the lines to be pursued, it is very unlikely that any sweeping reform will take place at their hands ; for the reason that had they appreciated the necessity for such schemes the councils would, of their own accord, have effected these years ago. It cannot, however, be said that in the important matter of conservancy municipalities have effected no advance. Forty-two night-soil, 19 rubbish, 18 sewage carts, and 54 public latrines were added during the year, whilst an addition of 2,900 houses attended to under the private scavengering system was made. 147 toties and 49 sweepers were added to the menial staffs. Sanitary peons and sanitary maistries as well as Sanitary Inspectors underwent reduction, in conformity with the policy of introducing a better class—Certificated Sanitary Inspectors—to take the place of the numerous low-paid and ignorant men till recently employed on sanitary inspection work.

The rules for guidance of municipalities as to cholera prevalence were finally approved by Government (G.O., No. 1536-M., dated 9th September 1896). Their sphere of utility has, however, been much cramped by Government permitting discretion to local authorities as to employment of the staffs with the consent of the Collector. Collectors are very human in this matter, and are liable to assume a safety from loss of life that is the result of the wish being the father of the thought, and, consequently, efforts to convince municipalities as to the necessity for employment of full staffs are at times delayed. The staff advised by the committee which sat on this subject was regarded by it as the minimum requirement, and it seems to me that to permit municipalities with the self-confidence of amateurs to modify this staff "in the interests of economy," is a great mistake in the interests of life. In prompt action is really the key to ultimate economy. It may be held that in the exercise of the right of self-government a certain amount of discretion is advisable ; but it seems to me that the matter is of provincial not solely local concern, and that, if a council is determined to effect economy by providing inadequate staffs for epidemics, it should not be allowed to do so to the detriment of its neighbours. What I now say would doubtless apply with equal force to the rules for combating bubonic plague where much the same staff and arrangements are held to be requisite (G.O., No. 1985-M., dated 18th November 1896). Yet, if hesitation occurs in this case in any municipality, the consequences to the presidency generally would shortly become undesirably obvious.

I trust I may not be misunderstood as to economy. This is, of course, essential on all occasions when dealing with public money. But calculation shews that the expenses of meeting an ordinary epidemic of cholera under the system required is not beyond the means of a municipality, provided their funds are in all other respects carefully managed and *proportionately* spent, and when, in rare cases, notwithstanding this care, the council is in the unfortunate position of saying it really has no funds, it seems to me but reasonable that rather than they should employ inadequate measures the credit of the council should be pledged in obtaining a loan.

During the year the public water-supply works at Trichinopoly and Dindigul were completed and opened. Waterworks were also in progress at Conjeeveram and Kurnool. No improvements were made in the sanitary condition of the town of Madras, but a scheme for the sewerage of the city received the sanction of Government. Preliminaries seem to have been settled as to the erection of incinerators for the consumption of the town rubbish. The supply available to the inhabitants of the present unfiltered

and but partially protected water-supply in certain areas was rendered more constant by increasing the size and number of mains. Calicut erected a Silchar incinerator, and received sanction from Government for the conservancy-tramway suggested by me in 1893.

Pending the effecting of complete schemes of sewerage in municipal towns, it cannot be expected that much advance can be made as to sewage farming. Nevertheless, it has been pointed out to municipalities that much can be effected by extending existing systems sufficiently to serve suitable plots of land. Schemes for disposal by filtration of sewage from a small area of the town of Kumbakónam, and by improvement of existing arrangement at Tanjore, were discussed by the Sanitary Board during the year, but they have not been put into execution. Filtration of sewage is effected with good results at Vizagapatam previous to its entrance to the neighbouring swamp, where it was formerly a great nuisance, and at Vizianagram before entering into the Pedda Cheruvu. The former town has selected a place for a sewage farm, and has submitted a requisition under the Land Acquisition Act. At Vizianagram and Bellary filtration of sewage at households is also pursued with satisfactory results. At Rajahmundry the municipality opened during the year an experimental plot of one acre, which is cultivated by sewage that was formerly thrown hither and thither in waste places. The result, as I found on a late inspection, is a magnificent crop of vegetables, which are being sold at profit. The council now intends to extend the area. The plot taken up under ordinary systems of cultivation, would have been worthless, being almost solely sand. The sewage farm at Negapatam in Hathaway's Park continued to be a source of revenue to the municipality; Rs. 415 being realized from this source during 1895–96. Erode practised the cultivation of reeds successfully under sewage. The use of nightsoil and rubbish for cultivation advances in appreciation year by year. During 1895–96 the sum of Rs. 28,484 was realized by municipalities under this head against Rs. 24,755 during 1894–95.

The following statement shews allotment and expenditure for sanitary purposes during 1896:—

	1895–96.		Rate per cent. of expenditure to total allotment.	1896–97.		Rate per cent of expenditure to total allotment.
	Amount sanctioned.	Amount expended.		Amount sanctioned.	Amount expended in nine months end ng with December 1896

It cannot be said that results acquired so far are very striking. No other than a mediocre result from sanitary works in this Presidency can, however, be expected, so long as they are not constructed so as to involve not the major portion of towns but the whole, so long as the facilities afforded are not such as to permit of free use of the water by the inhabitants in all parts of the town and at all times of the day, and, above all, so long as the Municipal Councils persist in retaining the old wells and tanks which the public water supplies should have replaced.

Coonoor.—I remarked as to Coonoor in my last report that it might be hoped that sewerage works were about to shew an influence upon the death-rate; this hope has, however, been set aside by the vital statistics for 1896. The increased death-rate is due to dysentery. The actual number of deaths (44) was small, but materially swells the total rate when calculated on a small population. I invited the Medical officer's attention to the matter, but he is not in a position to ascribe any special cause for the increase under this head—further than the existence of the well-known factor of impure water-supply, which is quite sufficient to account for the condition. The Coonoor sewerage works cannot be said to be complete in any sense; they do not embrace the entire town; the house connections are incomplete, and sanitarily very imperfect. The discharge of the town sewage untreated into the Coonoor stream is, in my opinion, a possible source of danger to Méttupálaiyam.

Cuddapah.—In the malarious town of Cuddapah, a decided improvement is noticeable, and this is the more remarkable, in that lessened mortality has been attended with an increased birth-rate. In this town extensions have been freely effected by the municipality, and the public water-supply is fairly well adhered to by the people. All this looks hopeful, but, as in the district itself there has also been a marked decline this year from malarious fever, it is too early to draw decided conclusions, except to further exhibit the well-known fact that a decrease of malaria favours the increase of the birth-rate. Certain insanitary conditions of the head works were brought to notice by me during the year, and Government directed the more serious to be at once rectified.

Kumbakónam.—These works are of a very partial description and effect the removal of surface water only, although in addition they may have a slight influence on sub-soil water within a limited area; but no permanent effect upon the health rate of the town can be expected from these works.

Madura.—Until the opening of Periyár irrigation works threw into the Vaigai (from the bed of which stream, Madura derives its supply by infiltration) its surplus and wastage, it cannot be said that the supply of water in this town by the water-works was sufficiently continuous as to form a sanitary factor of importance. The municipality still maintains its old wells and tanks open for public use. The head works and adjoining areas were found in the same unsatisfactory condition as on my previous inspection; but, I believe, action has since been taken to remedy matters.

Madras.—I have, in former reports, pointed out that no sanitary work as yet undertaken by the Municipality of Madras can be regarded as having fully met sanitary requirements, and that even such works as exist are not in respect to details so complete as to cause their beneficial influence to be felt in perfect measure. A decrease of the death-rate occurred in 1896, but this may fairly be ascribed to a return to a more normal condition of the sub-soil water level in a town where, on account of the filthy condition of the sub-soil, fluctuations are of peculiar importance.

Adóni.—The errors pointed out in the last report as existing in this work continued during the year. By December the water became undrinkable, owing to growth of masses of algæ and odour-producing micro-organisms in the storage reservoir. The action of the filter-beds was such as to remove them but partially; multiplication continued to take place in the service reservoirs, which, as formerly pointed out, were inappropriately constructed for storage of filtered water. I advised that the Council should be required to so alter the roofing that neither dust nor light should be admitted, and that the zinc-roofing unsuitable in reference to heat conduction should be removed. The Council in remarking on my report before transmission to Government denied the possibility of dust gaining entrance through a space of three inches throughout the length and breadth of the reservoirs, but thought blood-suckers—which are usually considerably larger in this presidency than dust particles—could gain admission. They rejected the light theory, which represents the outcome of the last seven years' labours of various bacteriologists, without argument, and desired that glass shutters should be employed. [The Sanitary Board has, however, since overruled this decision.] The use of a stick and tape by the overseer in charge in lieu of ordinary gauges does not seem, from the result attained by the filter-beds, to have conduced to his ability to control the

rate of filtration, when added to the other peculiarities of this filter-bed mentioned at page 44 of my last year's report.

Dindigul, Tanjore, Trichinopoly.—The water works of Dindigul, Tanjore and Trichinopoly have not been opened sufficiently long to permit of any opinion as to results being given. Up to date, formerly existing sources are largely utilized in all these towns, in addition to the "pipe" water. As in the case of Madura, the two last-named towns are supplied by infiltration from river sub-streams. Seeing that there can be no doubt as to conveyance of cholera by river water in this presidency, in accordance with the warning given at page 44 of my last year's report as to possible influence following the rapidly changing head of filtration, it would be advisable that more be known as to stoppage of the cholera microbe under these special conditions.

The following statistics have been supplied me by Surgeon-Lieutenant-Colonel W. O'Hara, District Medical and Sanitary Officer, Trichinopoly, shewing the influence of water on cholera attacks in that town. It will be seen that the "pipe" water has the advantage, but it is by no means such as ought to be demonstrable. The table, perhaps, is more an excellent statistical statement of how largely the people, instead of using a single supply, really use mixed supplies; but it is enough, I think, to dictate *caution*, as to adoption of this description of infiltration work in the shallow, sandy beds of rivers in this presidency without provision for subjection of the water to the action of ordinary filter-beds after gathering from the gallery. This, however, is a matter that, whilst I consider it necessary to warn concerning, can only be definitely answered by a series of bacteriological experiments :—

District boards.

Government, having disposed of the Amended District Municipalities Act, will, it is hoped, shortly be able to give attention to the amendment of the District Boards Act No. V of 1884. Until this is effected, sanitary advance in rural areas must necessarily be saddled with much difficulty. Equally on behalf of localities where fairs and festivals are held, it is hoped, Government will be able to deal with the promised Act on the lines of the Pooree Pilgrim Lodging House Act. Thus correctly equipped with legal power, it should be possible for a very decided advance to be made within a short period. In the meantime, in the absence of power to gather sufficient funds for general purposes, Government has considered it requisite that expenditure under sanitation in common with that under education and medical services should be curtailed, so that a minimum of 50 per cent. of the total land cess collections *plus* the net receipts from tolls of District Boards, shall be available for the better upkeep of communications. The effect of this order seems to me unfortunately to be that education suffers less in proportion to the other services, as the charges being in most part fixed permit of no reduction, whereas those of sanitation are not so and can readily be reduced. In consequence of this order, it is of little use to advise District Boards to employ either permanent sanitary staffs or those intended for combating epidemics, and indeed, the actual efforts made by Local Fund authorities to prevent the spread of the late epidemic of cholera were decidedly inadequate. Under the circumstances, all that can be done is to wait in patience till an improved Act gives the power of obtaining better machinery and more funds to work with in rural areas.

It is necessary for me to enter into the above explanation in reference to the falling off of expenditure under the head of sanitation under District Boards. Thus, against a total allotment of Rs. 6,96,498 for 1895 that for 1896 amounted to only Rs. 6,70,172 or 8·4 per cent. of the total income, against 9·2 per cent. of 1895. Unfortunately, the decrease of expenditure occurred chiefly under improvement of water-supply, as to the necessity for which there is undoubted urgency. Whilst funds have thus been diverted from sanitation, there has also been enforced by Government more judicious expenditure of funds available for conservancy. It was formerly a frequent matter to find that Taluk Boards sanctioned the employment of men in villages for the sweeping of rubbish, who would not remove much more dangerous material in the shape of fæcal matter. Such staffs have now been correctly modified. The tendency for unions to regard the fitting up of lamps as a first call upon their incomes has also been successfully curbed.

Village Sanitary Inspection Report books were in use in all unions in all districts of the presidency at the end of the year except in Vizagapatam, Anantapur and Cuddapah.* Assurances have been received from District Medical officers that arrangements will be completed shortly. In response to requests received from several officers, sample forms embracing all the required information were issued from this office for general adoption.

Personal Proceedings and General Remarks.

Of the total of 365 days, I was absent from head-quarters on inspection duty 210 days. During this period, I travelled 9,784 miles by road, rail and canal. The Deputy Sanitary Commissioner was absent from head-quarters a total of 155 days, and travelled 7,185 miles by road, rail, canal and sea.

Eleven municipalities were formally inspected and reports thereon were furnished by me. Twenty-five towns and villages were also inspected, and with the exception of nine were reported upon.

A number of localities were also inspected and were reported upon by the Deputy Sanitary Commissioner.

A total of 449 places were inspected by District Sanitary officers. Special parts of their reports were pressed on the attention of local authorities where it was found action was unduly delayed.

I should have accomplished the inspection of three more municipalities before the close of the year, but, with the approval of the Government, I undertook a tour in the famine-stricken districts. Before the close of the year, I had inspected certain of the famine works in the Bellary and Adóni taluks. From what I saw of the working of the Famine Code in these taluks and subsequently, I was enabled to advise Government to depart from the arrangements laid down in the Famine Code as to diet and other important particulars.

Towards the end of September, the fact that bubonic plague had appeared in Bombay induced me to issue circulars to all local authorities containing descriptions of the disease, stating the precautions and preventive measures to be taken, and asking that all persons should be warned of the risk they run in going to Bombay. Notices to the latter effect were also posted in all railway stations throughout the Presidency, with the consent of the Railway authorities. In consultation with the District Medical and Sanitary officers concerned, I instituted a system of inspection of passengers at Adóni, Guntakal, Bezwada and Hospet. The names and addresses of all persons proceeding to Madras town were sent on by guards of trains to a Special Inspector of the Municipality of Madras which, in common with all mofussil municipalities, I advised to institute a system of inspection at railway stations followed by domicilliary visits for ten days of all arrivals from suspected or infected areas. All Port officers were warned by me, as, indeed, they had also been in July 1894, of the advance of plague, and they were exhorted to use their powers as to quarantine under G.O., No. 9, Marine, dated 17th January 1890. The necessity for prompt cleansing of municipal towns and the destruction of rubbish and packing materials from the houses of merchants dealing with Bombay was particularly impressed upon municipal councils. Government was advised to sanction a set of rules on the lines of those already in force for combating cholera with suitable alterations in respect to staff and methods. These rules received the approval of Government (G.O., No. 1985 M., dated 18th November 1896), so that should at any time plague appear, each municipality will know what staff and *matériel* to employ in proportion to its

* Up to date no replies to queries have been received from Bellary, Kistna and Gódávari.

population and what action is requisite. These and other measures were ultimately reinforced and enlarged in scope by the direct action of Government armed with powers under the Epidemic Diseases Act of 1897.

Endeavours to control the sanitary care of festivals continue to be satisfactorily recognized by local officials concerned. The great festivals at Tiruvannámalai and Tirupati again passed off without being attended with outbreaks of cholera, all local authorities concerned co-operating cordially in effecting my recommendations. In the case of the latter, there was good reason to regard the arrangements as conducive to this result. A party of pilgrims arrived at Upper Tirupati from Mysore just before the festival, and were attacked with cholera. So far the circumstances of the cholera outbreak in 1893, and those of 1896 were the same; but, in the latter case, there was a sanitary staff already on the spot, in the former case, none had been appointed. Thus the Pushkaram tank—the medium of spread in 1893—escaped infection, as full precautions were at once taken by the staff.

Considerable time was consumed in correspondence with, and in personal visits to, Kumbakónam on the subject of the Mahamagam festival, where a collection of three to five lakhs of persons usually assemble. The Municipal Council, which represents the most highly educated population of Southern India, proved most obstructive and dilatory in effecting recommendations, even where these were of the most obvious and simple character, and, as the sequel told, the festival found them in a state of unpreparedness that operated most adversely. I trust future legislation as to festivals will prevent important sanitary arrangements being subject to undefined standards evolved by local councils as to their necessity.

The movement as to obtaining correctly-instructed Sanitary Inspectors for local authorities inaugurated by Government under my advice in 1894 has progressed successfully. Fifty-two men gained the necessary certificates in 1896. Government has now made it compulsory that at least one trained man shall be entertained in each municipality, and has advised Councils to replace those now in employ by men of the certificated class. As an incentive to this end, men who have had less than five years' service are required to pass the qualifying examination or quit the service. Twenty-eight Councils now possess Certificated Sanitary Inspectors. Four are employed by District Boards, and provision has been made in the budget for 1897–98 for 5 more.

During the epidemic of cholera in the Bellary district, 14 Certificated Sanitary Inspectors were entertained by the District Board, although their services unfortunately were engaged late in the day. One was also employed by the District Board, Gódávari, during the outbreak of cholera following the Pushkaram festival.

Reports of their conduct and professional acquirements received from District Medical and Sanitary officers and from local authorities have been very satisfactory, although there have been a few notable exceptions.

By the end of December, 85 candidates had enrolled their names for the course of training in 1897. Of these, 61 were private students who paid for their course, 31 had passed the Madras University Matriculation examination, one was a B.A., four were F.As., two had undergone the full course for the L.M. & S. of the Madras University, and eight were qualified Hospital Assistants. Many of the matriculates held certificates of efficiency in Surveying, Construction, Estimating, Drawing and other engineering subjects. There is thus room to believe that, if further encouragement be given by local authorities and by Government, a well-educated class of men could be constantly secured as Sanitary Inspectors. It now remains to require that either additional subjects be uniformly passed before entrance to the Hygiene class is allowed, or that this course be prolonged, so as to include them.

Towards the end of the year, the constitution of the Sanitary Board underwent a change by removal of the Sanitary Commissioner and the Sanitary Engineer to Government from the Board, and according to them the position of advisers to the Sanitary Board. This step was apparently the outcome of endless differences of opinion that might naturally be expected to arise where two engineer members were associated with a single sanitarian. As the Sanitary Board will present its own report to Government, and is responsible for advising as to sanitary works, I have not thought it necessary in the body of this report to enter into any details as to proposed improvements. Indeed, I could not do so, as of the ultimate opinion arrived at by the Sanitary Board on schemes presented to its scrutiny, I am under the present system kept in ignorance.

The question of the quantity of water likely to be consumed by municipalities is one open to doubt. There is no town in the Madras Presidency that has been provided with a water-supply that does not adhere to the objectionable arrangement (but in some cases an

arrangement not to be avoided on account of the inadequacy or untrustworthiness of the supply) of maintaining the old sources of supply side by side with the new. The result is that any estimate of what would suffice for a native population founded upon existing sources of information derived from expenditure in public water-supplies, cannot be otherwise than misleading. For example, in Madras, in a native house of a respectable, but not wealthy, class having a public water tap within 10 yards of it, the supply per head was found to be eleven gallons from a well in the premises, and 2·20 gallons from the public supply, on observation carefully conducted and extending over a period of ten days: in another instance where only the public supply was used, the consumption was found to be 14·61 gallons per head—the experiment also extending over ten days. Again, in such water-works as have been formed in the mofussil, the works themselves do not offer the facilities, nor have the municipalities the apparatus, nor at present the wish to largely use the supply for municipal purposes. With the object of throwing some light on this important and strictly sanitary question, I circulated to District Sanitary officers forms asking for measurements of the water supply of households for seven-day periods, under the superintendence of medical subordinates. For facilitating calculations an arithmetical table, and forms setting forth the various domestic purposes to which water is put, were supplied. Altogether, the results of 65 observations extending over the required period were received. The total average shewed that the amount required for domestic consumption under the ordinary conditions of native life was 16·9 gallons per head per day. This represented water drawn in all instances by manual labour and carried over varying distances, and it certainly would result, as experience elsewhere has shewn, that when these difficulties were removed a large increase would be required. Taking, therefore, into consideration the amount necessary for municipal purposes and for "unavoidable waste," and excluding special demands for manufactures and fires, it is probable that 25 gallons would prove a fair supply, and 20 gallons a minimum safe supply for municipal towns. In my humble opinion if water-works in this Presidency are to be trustworthy factors in diminishing the death-rate, they must provide sufficient water for all domestic purposes, and not entail the occasional or habitual use of inferior sources they were intended to supplant. Mechanical arrangements must be provided in anticipation of the period when the advantages of free use for municipal purposes will be fully appreciated; and this may be expected to occur when the facilities offered by sewerage works will induce free consumption under this special head. For this reason, within reasonable limits as to economy, the smaller sizes of pipes should not be introduced into a system to an extent to prohibit the free use of hydrants. Whilst the liberal use of water means health to the individual in private life, it can only be by its equally liberal employment for municipal purposes that a correct sanitary condition re-acting upon the total community can be hoped for. In making these remarks, I, of course, assume, as above suggested, that increased use of water will coincide with provision in towns for its correct removal by sewerage works.

The bacteriological apparatus sanctioned by Government has not yet arrived for use of this office, but is expected shortly. Diagrams and other materials are also expected that will enable advice given to municipal councils to be illustrated during conferences with them before leaving towns that have been inspected.

In accordance with the orders of Government in reference to my suggestion conveyed in the report for 1894, I submitted to Government a simple and inexpensive instrument and a detailed scheme for measurement of sub-soil water fluctuation at chief points throughout the Presidency. The matter is still under consideration.

Sanitary Engineering (1896).

During the year 1896 surveys for water-supply or drainage were completed for seven municipalities, as against three in 1895, irrespective of surveys in progress for one municipality; and additional levels were taken for the water-supply scheme of two municipalities and for the drainage of one. Of the six schemes, costing Rs. 19,85,542, submitted to the Sanitary Board, four—viz., for the water-supply of Srirangam, Kumbakonam, Gudiyattam, and the construction of filter beds and a service reservoir at Cuddapah—were submitted to Government by the Board, and the remaining two schemes for the water-supply of Tuticorin and Bellary were under their consideration; besides these, schemes for the water-supply of Nagapatam and Coonoor, and for the drainage of Cuddapah were under consideration, and revised estimates for five schemes of water-supply, costing Rs. 17,36,569, as against Rs. 15,92,430 (originally estimated) were

prepared. A scheme for supplying the town of Penukonda with water was investigated and the plans and estimates for the work were prepared and submitted to the Sanitary Board. The scheme for the water-supply of Vizagapatam, as revised, was sanctioned for execution by the Public Works Department. Four water-supply works, estimated to cost Rs. 11,32,309 in the aggregate, were under execution ; of these the Trichinopoly and Dindigul works were completed, while fair progress was made with the Kurnool and Conjeeveram works.

The Sanitary Board scrutinised plans and estimates for 72 municipal and 87 local fund works estimated to cost Rs. 2,75,331 in the aggregate. The funds at the disposal of local bodies for sanitary purposes being very limited, the Board found it necessary to approve of a certain number of schemes which, though not in all respects sanitarily perfect, were nevertheless calculated to effect a distinct improvement in the sanitary condition of the areas concerned. Type plans for hospital buildings were prepared by the Consulting Architect to Government in consultation with the Sanitary Commissioner and the Sanitary Engineer and were under the consideration of the Sanitary Board at the end of the year. Type designs for nineteen sanitary works were issued by the Board during the year.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1896.

(*Surgeon Lieutenant-Colonel J. W. Clarkson.*)

General Population.

European and Eurasian Vital Statistics.

By the census of 1891 the European civil population in the Bombay Presidency exclusive of cantonments in quasi-foreign territory, numbers 18,486 persons. During the year 1896, 294 births and 303 deaths were recorded against 358 and 357 in 1895 respectively—a birth-rate of 15·95 per 1,000 against 19·37 in 1895 and a death-rate of 16·44 against 19·31. By sexes 161 males and 133 females were born against 191 and 167 respectively in 1895, and as regards deaths, 188 males and 115 females died against 219 and 138 respectively in 1895.

The Eurasian population numbers 8,519 persons by the census of 1891, and during the year 1896 the births amounted to 156 against 164 in 1895 and the deaths to 195 against 219—the rates respectively of 18·31 per 1,000 against 19·25 in 1895 and 22·89 against 25·71. Of those born 99 were males and 57 females against 94 and 70 respectively in 1895, and as regards deaths 111 males and 84 females died against 113 and 106 respectively in 1895.

A table is appended shewing the European and Eurasian population in each collectorate and the births and deaths for the year 1896 compared with the births and deaths in 1895, and another table following shews the deaths by causes and the ratios in 1896 compared with 1895 :—

* As the population for the Cantonments in quasi-foreign territory is not obtainable, the ratio of deaths cannot be worked out.

Of the 13 deaths registered from cholera among Europeans, eight occurred in the collectorate of Poona, three in Nasik, one in Surat and one in Broach. Of the five deaths from cholera recorded among Eurasians, four took place in the city of Bombay and one in the collectorate of Dhárwár.

NATIVE POPULATION.

Births.—In the Presidency of Bombay, including Sind, during the year 1896, there were 691,847 births registered against 674,304 in 1895. The recorded births for the year under report were thus 17,543 in excess of the number registered in the previous year, and exceeded the mean of the preceding ten years ending 1895 by 50,021. By sexes there were 359,097 males and 332,750 females against 350,115 and 324,189 respectively in 1895.

The following table shews the number of births registered in each year from 1886 to 1896, their ratios per 1,000 of population and the proportion of males to females :—

Years.	Population.	NUMBER OF BIRTHS REGISTERED.			RATIO PER 1,000 OF POPULATION.			IN EVERY 100 BIRTHS THERE WERE		For every 100 male Births the females were
		Males.	Females.	Children.	Males.	Females.	Children.	Males.	Females.	
1886	16,454,414	303,376	278,177	581,553	18·44	16·90	35·34	52·17	47·83	91·69
1887	16,454,414	327,500	300,693	628,193	19·90	18·27	38·18	52·13	47·87	91·81
1888	16,454,414	330,316	304,377	634,693	20·07	18·50	38·57	52·04	47·96	92·15

1892	18,820,346	337,150	313,517	650,667	17·91	16·66	34·57	51·82	48·18	92·99
1893	18,820,346	345,424	318,881	664,305	8·35	16·94	35·30	52·00	48·00	92·32
1894	18,820,346	342,911	317,357	660,268	18·22	16·86	35·08	51·94	48·06	92·55
1895	18,820,346	350,115	324,189	674,304	18·60	17·23	35·83	51·92	40·08	92·59
Mean for 10 yrs.	17,637,380	333,809	308,017	641,826	18·93	17·46	36·39	52·01	47·99	92·27
1896	18,820,346	359,097	332,750	691,847	19·08	17·68	36·76	51·90	48·10	92·66

The recorded birth-rate for the year was 36·76 per 1,000 of population against 35·83 in 1895 and a mean of 36·39 for the previous ten years.

Of the 24 collectorates and districts the number of recorded births in 1896 was higher than in 1895 in 16, viz.:—

Khándesh.	Ratnágiri.	Panch Mahals.
Násik.	Kánara.	Ahmedabad.
Thána.	Surat.	Karáchi.
City of Bombay.	Broach.	Shikárpur.
Kolába.	Kaira.	Upper Sind Frontier.
Poona.		

The remaining 8 collectorates and districts shew a decrease as compared with 1895. There appears some improvement in the registration of births in Sind, especially in the collectorates of Karáchi and Shikárpur and in the district of Upper Sind Frontier. In the collectorate of Hyderabad and in the district of Thar and Párkar the registration of births is apparently defective. The city of Bombay shews slight improvement in the registration of births over last year. The recorded birth-rate per 1,000 of population for the city of Bombay was 19·35 against 19·07 in 1895, and the mean for the last ten years ending 1895 was 19·29.

As regards the comparative low birth-rate in the collectorates of Belgaum, Dharwar and Bijápur, the Deputy Sanitary Commissioner, Southern Registration District, states: "The "decrease in the number of births recorded in Belgaum, Dhárwár and Bijápur may be chiefly "ascribed to the failure of the crops throughout Bijápur, whilst in Dhárwár and Belgaum a "large number of villages in the eastern tálukas were seriously affected. Under these "circumstances, owing to the movement of many of the villagers to the Mulad with cattle "and of others to distant places in search of work, it is but natural that the birth-rate "should suffer. Many births must in consequence have escaped registration."

As regards the decrease in the number of births recorded in the collectorate of Hyderabad and the Thar and Párkar District, the Deputy Sanitary Commissioner, Sind Registration District, remarks that "the alleged causes of decrease being the absence of rain and "consequent scarcity of fodder in the latter, and the prevalence of fever in the former."

The recorded birth-rates among the urban and rural populations of the Presidency were 29·61 and 37·76 against 29·04 and 36·78 in 1895. Except in the collectorates of Ratnágiri, Dhárwár, Kaira, and throughout Sind, except in the Upper Sind Frontier, the birth-rates were higher among the rural than in the urban population.

Out of 56 towns in the Presidency, 16 had a birth-rate exceeding 40 per 1,000. Thána, Násik and Bombay have still very low birth-rates.

Deaths.—Among the civil population in the rural, town and cantonment circles in the Presidency 596,472 deaths were registered during the year 1896. In 1895, 538,540 deaths or 57,932 less than in 1896 were recorded.

The following statement shews the number of deaths recorded in each year since 1886 :—

1886	... ...	381,185	1890	... ...	463,616	1894	... ...	607,179
1887	... ...	455,261	1891	... ..	513,132	1895	... ...	538,540
1888	... ...	468,039	1892	... ...	611,742	1896	... ...	596,472
1889	... ...	518,562	1893	... ...	511,831			

Of the total deaths registered 312,458 occurred among males and 284,014 among females, against 280,866 and 257,674, respectively, in 1895.

The computed death-rate per 1,000 of population in 1896 was 31·39 against 28·61 in 1895 and a decennial mean of 28·74. The millesimal rates of males dying to males living was 32·09, and of females dying to females living 31·27. In 1895 these ratios were respectively 28·84 and 28·37. For every 100 females who died 110·01 deaths among males were recorded, but these proportions vary considerably in the following collectorates :—

In Khándesh	the ratio of male to female deaths was		112·42	per cent.
„ Bombay	do.	do.	120·97	„
„ Ahmednagar	do.	do.	111·31	„
„ Kaira	do.	do.	119·41	„
„ Panch Mahals	do.	do.	113·45	„
„ Ahmedabad	do.	do.	112·08	„
„ Karáchi	do.	do.	119·54	„
„ Hyderabad	do.	do.	127·87	„
„ Thar and Párkar	do.	do.	122·98	„
„ Shikárpur	do.	do.	119·37	„
„ Upper Sind Frontier	do.	do.	119·64	„

The recorded death-rates per 1,000 of population were higher than in 1895 in all the collectorates and districts, except in the collectorates of Ahmednagar, Sholápur, and

Sátára. The recorded death-rate per 1,000 of population in 1896 was higner than the annual mean of the preceding ten years in the following collectorates and districts :—

Khándesh.	Poona.	Kaira.
Násik.	Sátára.	Panch Máhals.
Thána.	Ratnágiri.	Karáchi.
City of Bombay.	Belgaum.	Thar and Párkar.
Kolába.	Bijápur.	Upper Sind Frontier.
Ahmednagar.	Surat.	

In the collectorates of Broach, Ahmedabad and Shikárpur the recorded death-rate for 1896 was about equal to the annual mean for the preceding 10 years. In the collectorates of Sholápur, Dhárwár, Kánara and Hyderabad, the recorded death-rate for 1896 was lower than the annual mean for the preceding 10 years ending 1895.

Deaths by ages.—The mortality amongst children under 5 years of age is high and amounts to 40·49 per cent. of the total deaths, and the infantile mortality under one year is 179·38 per 1,000 living. Under one year the percentage on total deaths was 20·46 against 22·30 in 1895, and in the age period 1 to 5 years the percentage was 20·03 against 21·13 in 1895. The period of greatest immunity was, as last year, in the age period of above ten and under fifteen, the rate being 10·16 living or 3·10 per cent. on total deaths. Among old people of 60 and upwards, the percentage on total deaths was 13·57 against 14·81 in 1895.

Deaths by caste or class.—According to the Census of 1891, the Mahomedan population numbered 3,501,910 persons, amongst whom in 1896, 85,746 deaths were recorded against 71,965 in 1895, the death-rate being 24·48 per 1,000 of population against 20·55 in 1895. The Hindu population amounted to 14,897,629 persons, amongst whom 502,590 deaths or 33·74 per 1,000 of population were recorded. In 1895 the total deaths amongst this race were 459,918, equal to a death-rate of 30·87 per 1,000 of population. Amongst the Christian population, numbering 122,089 persons, 3,016 deaths were reported during the year against 2,509 in 1895, the death-rate being 24·70 against 20·55 in 1895. Under the heading "Other Castes" are included all those not belonging to either of the above sects, who, by the census of 1891, numbered 298,718 persons, amongst whom, during 1896, there were 5,120 deaths against 4,148 in 1895, the death-rate being 17·14 per 1,000 of population against 13·88 in 1895. Among Mahomedans the maximum death-rate during the year (53·08 per 1,000) took place in the city of Bombay, and the minimum (16·04) in Hyderabad. In 1895 the maximum death-rate was 48·84 in Násik and the minimum 13·10 in Hyderabad. Among Hindus the maximum death-rate (44·77 per 1,000) was in the collectorate of Násik and the minimum (23·53) in the Thar and Párkar District. In 1895 these rates were Sholápur (40·22) and Thar and Párkar (17·46) respectively.

As regards the disproportion in the death-rates of Mahomedans and Hindus in Sind, the Deputy Sanitary Commissioner, Sind Registration District, refers to his remarks made last year and considers that the discrepancy is due to defective registration in the rural circles, it being there in its earliest infancy and in the hands of tappedárs and village pátils and mukhis over whom it is difficult to exercise supervision as regards death-rates.

Deaths by causes.—The subjoined table shews the deaths in 1896, arranged according to the specified causes laid down by the Government of India, and contrasts with the results for 1895, and the mean of the preceding ten years. The causes of death will be briefly noticed in the next section :—

Causes of deaths.	Mean for 10 years, 1886–1895.		1895.		1896.	
	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.
Cholera	22,008	1·26	8,890	0·47	35,404	1·88
Small-pox	3,153	0·18	2,299	0·12	6,443	0·34
Fevers	357,247	20·25	388,848	20·66	412,229	21·90
Dysentery and diarrhœa ...	38,504	2·18	35,348	1·88	36,046	1·92
Injuries	5,840	0·33	6,051	0·32	6,238	0·33
Other causes	80,156	4·55	97,104	5·16	100,112	5·32
All causes	506,908	28·74	538,540	28·61	596,472	31·69

Chief Diseases.

During 1896 cholera caused 35,404 deaths throughout the Presidency, while in the preceding year, 8,890 deaths were registered from this disease. The epidemic prevailed chiefly in the Poona, Bijápur, Sátára, Belgaum, Ahmednagar and Dhárwár Collectorates. Cholera.

In December 1895, deaths from cholera were reported from fourteen collectorates. Of these collectorates cholera was reported in Násik, Kolába and Ratnágiri on the 1st January, in Bijápur, Poona and Thána on the 2nd January, in a town of Ahmedabad on 7th (only one death), Sàtára Collectorate on 10th and Bombay City on 17th, practically a continuation from the previous year. Khándesh, Ahmednagar, Sholápur, Belgaum and Kaira Collectorates returned no cholera deaths for the month of January. The other collectorates were free from cholera at the end of last year. The cholera in Thána, Sátára, Bijápur and Ahmedabad, however, stopped during the month and no cases were reported during February, but continued in Násik, Kolába, Poona and Ratnágiri Collectorates and Bombay City. In March, however, in addition to the above, the collectorates of Khándesh and Ahmednagar were affected and the disease appeared again in Thána and Bijápur. In April cholera was first reported for the year in the districts of Dhráwár and Surat and re-appeared in the Ahmedabad Collectorate, besides continuing in the districts affected in March and a much increased mortality took place.

In May the outbreak continued in the above collectorates and in addition the appearance of the disease for the first time during the year was reported in Sholápur, Belgaum, Broach, Kaira and the Panch Maháls, and the mortality was double that of the previous month. In June, 5 deaths were reported from the Thar and Párkar District of Sind, but with this exception no other death from this cause took place in Sind during the year. The whole of the rest of the Presidency was affected during this month and continued to be so during the months of July and August, the mortality reaching the highest point in July and declining somewhat in August. In September, though all the districts except Ahmedabad returned cholera deaths, there was a large decrease in the mortality; still further decrease occurred in October, and in December the total deaths recorded were 911 from 9 districts only.

By seasons, 23,501 deaths occurred in the rainy season of 122 days, and 8,850 in the hot and dry season of 61 days.

Out of the 21,608 villages in the districts affected by cholera, 2,642 or 12·23 per cent. were attacked during the year. The highest percentage took place in the Bijápur Collectorate, where out of the 1,110 total villages 466 or 41·98 per cent. were affected. In Poona, out of 1,187 total villages, the disease appeared in 357 or 30·08 per cent. In Belgaum, Sátára, Ahmednagar, Sholápur, Surat, Broach, Dhárwár and Ahmedabad the percentages were respectively 22·67, 21·22, 15·99, 12·90, 12·20, 11·66, 10·85 and 10·56; whilst in the remaining 9 collectorates the percentages were below 9.

During 1896 there were 6,443 deaths from small-pox (3;417 males and 3,026 females) against 2,229 in 1895 and a decennial mean of 3,153.

In every district and in all the collectorates excepting four, viz., Kolaba, Sholapur, Bijápur and Kánara, the number of small-pox deaths has increased during the year. In the Western Registration District, the disease attained a ratio of 0·65 per 1,000 against 0·30 in 1895 and a decennial mean of 0·34. In the Gujarat Registration District the ratio was 0·48 against 0·05 in the previous year and a decennial mean of 0·06. In the Sind Registration District it was 0·31 against 0·07 in the previous year and a decennial mean of 0·15. In the Southern and Central Registration Districts the ratios per 1,000 of population were respectively 0·19 and 0·09 against 0·06 and 0·08 in the previous year, and 0·17 and 0·13 the decennial mean. In the collectorates the highest death ratio 0·94 took place in the Khándesh Collectorate and the lowest 0·01 in two collectorates of Sholápur and Bijápur. The Presidency rate was 0·34 against 0·12 in the previous year and 0·18 the decennial mean. Small-pox.

According to age, 29·50 per cent. of the small-pox deaths occurred amongst infants under one year of age, whilst 51·78 per cent. took place among children over one and under 12, the remaining 18·72 per cent. being among persons over 12 years of age.

During 1896, 215,723 males and 196,506 females, or a total of 412,229 persons, were reported to have died from fever against 388,848 in 1895, shewing an increase of 23,381 deaths for the year, the mean for the previous ten years being 357,247. Fever.

In the Gujarát Registration District fever caused a high mortality, 29·42 per 1,000 during the year against 22·68 in 1895 and the decennial mean 27·75. In the Western Registration District the death ratio was 24·08 against 21·49 in the previous year and 19·69 the ten years' mean. In the Central Registration District the ratio for the year was

21·40 against 24·45 in the previous year and 19·81 the decennial mean. In the Sind and Southern Registration Districts the respective ratios for the year were 19·34 and 14·87 against 15·81 and 16·07 in the previous year and 17·77 and 16·56 the ten years' mean. The Collectorate of Broach heads the list with the high ratio of 33·23 against 23·85 in 1895 and 32·81 in the previous ten years ; and the lowest ratio 10·95 was attained in the town and island of Bombay and 13·72 in the Belgaum Collectorate, the Presidency rate being 21·90 against 20·66 in the previous year and 20·25 the decennial mean.

The number of deaths from fever and the death-rate per 1,000 of population though less in the famine districts of Ahmednagar, Poona, Sholápur, Sátára in the Central Registration District and Belgaum and Bijápur in the Southern Registration District, was higher in every other district than the last year. When compared with the previous year the increase amounts to 23,381 deaths in the total number of the Presidency. Taken by registration districts, Western, Gujarat and Sind Districts shew increased mortality. For this increase the Deputy Sanitary Commissioner, Gujarát Registration District, observes as follows :— "The years 1892, 1893 and 1894 were years of more than average rainfall and shew a "high death-rate from fever, whereas 1895, with a rainfall below the average, shews a large "decrease in fever mortality." It might, therefore, naturally be supposed that the effects of the dry year would be felt in the first half of the following year, and when this year 1896 also passed with a rainfall still more scanty than its predecessor, the effect on the fever mortality should have been still more marked. According to the returns there is an increase in fever mortality in all the collectorates, resulting in a total increase for the district of 20,876. This increase is most marked in the first nine months of the year, the largest addition being in the months of June, July and August, whereas for the last three months of the year, the recognized months of malaria, the increase is least. These apparently contradictory figures admit of explanation to some extent. The returns for the last three months of both years 1895 and 1896 shew comparatively little difference, and these are the months during which it is generally recognized that malarial fever is most prevalent. During the first nine months of the year small-pox and cholera were prevalent in an epidemic form throughout the district, and it is possible that many deaths due to one or other of these diseases were entered as deaths from fever. Moreover, there are many villages in which every death is returned as due to fever and consequently in such villages a large proportion of deaths must be wrongly entered. It is worthy of note that during the last three months of the year, when malarial fever is most prevalent, the returns for the two years—1895 and 1896—correspond fairly accurately, while the large divergence occurs in the latter part of the cold weather when deaths from chest affections are most liable to occur and in the hot weather and first months of the monsoon when epidemic diseases are most prevalent. Additional evidence in favour of this explanation is offered by the following figures which shew the returns from fever during the last three months of the five years from 1892 to 1896 :—

Year.	Deaths from fever during October, November and December.
1896	... 19,026
1895	... 18,703
1894	... 27,396
1893	... 25,879
1892	... 39,448

"The years 1892, 1893 and 1894 were years of more than average rainfall, and we see the "effects in the large increase in fever mortality during the last quarter of the year. In "1895 and 1896 the rainfall was scanty and a consequent diminution in deaths from fever "during the same months. Therefore, I think, it is not possible to accept the returns of "deaths from fever during 1896 as representing the mortality from malarial fevers."

In the first seven months from January to July the deaths from fever were above the corresponding months of 1895 and the ten years' mean. In August they are only less by two than 1895, but they are above the mean by 5,413. In September they are less by 3,938 than 1895, but they are above the mean by 158. During the months of October, November and December they are both below the 1895 and the mean figures. It will be noted that the fever mortality which began to rise in December 1895 continued to increase in January 1896 (the maximum for the year) and continued at a high level till March, when a decrease is shewn ; the lowest fever mortality appears, as usual, in June. In July and August, the period of heaviest rainfall, a rise is observed, but in September, when the rains failed, a decline takes place.

In accordance with the desire of the Army Sanitary Commission a slight meteorological sketch for the year is here appended.

For the first four months of the year there was practically no rain, a higher maximum temperature is shown, and the range of the temperature is also higher than last year. In May a few showers occur, with the effect of slightly lowering the temperature and diminishing the range. Throughout the Presidency the rains began early in June and, in the districts of Násik, Ahmednagar, Poona, Sátára, Belgaum and Dhárwár, the fall was above the average. In Khándesh and Sholápur it was about the average, in Bijápur and the northern parts of Surat below it. In the month of July the rainfall, except in Sholápur and Bijápur where it was insufficient, was far above the average and in some districts excessive. In the early part of August also rain fell during the first part of the month, being above the average in Poona, Belgaum, Dhárwár and the southern parts of Surat, but towards the end of the month the rain stopped, and the rainfall in September and October throughout the districts was very slight and deficient. In the month of November 6 inches and 76 cents. fell in four days in Sholápur, and in Bijápur there were the usual showers. The maximum temperature diminished with the rainfall and also did the range, but increased again as the rain ceased in August. The price of food-grains also very seriously increased ; wheat which was selling in January from $18\frac{10}{16}$ to $12\frac{15}{16}$ seers sold in December from $9\frac{5}{16}$ to $6\frac{15}{16}$ seers per rupee. Second sort rice, which varied from $12\frac{9}{16}$ to $8\frac{5}{16}$ seers in different districts, rose to 10 to $6\frac{1}{2}$ seers. Jowári which sold from 28 to $18\frac{1}{2}$ seers rose to $12\frac{1}{8}$ to $9\frac{3}{8}$ seers a rupee, and bajri, which varied from $23\frac{1}{4}$ to $14\frac{3}{16}$ seers for a rupee in different districts in January, rose to $8\frac{15}{16}$ and $9\frac{1}{4}$ seers in the same districts.

Plague.

First Appearance of Plague in the City of Bombay.—On the 29th September 1896, a committee, consisting chiefly of medical men, assembled in Bombay by order of Government, declared plague to exist in Bombay. The existence of this disease had been notified about a week previous by Dr. Viegas, a local practitioner, and Dr. Surveyor working with him had isolated a bacillus resembling that of plague as discovered by Dr. Kitasato of Japan, and this was confirmed later by Surgeon-Captain Childe, M.B., Professor of Pathology in the Grant Medical College.

How the disease was brought into Bombay cannot be ascertained. Various theories have been brought forward, that it was brought in by rats, of which large numbers of dead ones were observed, by the grain supply, by sewers which had become infected. I do not propose to discuss all these theories, which will be argued out in time and supported or otherwise by the investigation of the scientific Plague Research Committee now at work in Bombay. I see no reason why the disease should not have been introduced into Bombay by the usual agency of human intercourse. No one suspected the disease, nor did the weekly death returns shew anything very abnormal almost up to the date of the discovery of the existence of plague. There is no reason why a case coming from an infected locality, say on board ship, for instance, may not spread the disease to fellow passengers, and these infected land without notice. Once the infection was introduced, and had time to establish itself, there is every facility for its propagation as large numbers overcrowd into badly ventilated rooms, and not only this but the ground itself being damp and the soil very contaminated, the vitality of the inhabitants is lowered by their bad environment and perhaps still further impoverished by insufficient or innutritious food. That the disease is chiefly communicated from one person to another is, I think, clear. That it may be conveyed by air from one person to another is still open to doubt, but that the poison is in the discharges of the sick there is no doubt, and the casual way in which these are removed or left on clothing is one of the chief causes of propagation among a population overcrowding into badly ventilated dwellings. The year's weekly mortality for the city as compared with corresponding weeks of the previous year shews, with three exceptions, an increase which becomes marked in March and continues so to the end of April, and then a drop below last year's figures almost to the end of June. Then, again, the mortality commences to exceed that of the previous year, shewing a marked rise at the end of August with a drop in the succeeding two weeks, resembling what occurred in the April previous, but after that the mortality again rose and Dr. Viegas states that he saw his first plague case on 18th September. After which other medical men also recognized the disease which was declared to exist on the 29th of the month. Compared with the mean of the previous five years the average weekly mortality of the present year exceeded the mean to the end of April. During May and almost to the end of June the average weekly mortality

was about the same as the five-year mean, being less in three instances and being exactly the same as the mean for the week ending 19th May. From the end of June began the gradual rise which soon far exceeded the mean. The rise in the weekly mortality shewn to have occurred in the early part of the year (6 weeks—March–April) was most marked on the 2nd Nágpáda, Kámáthipura and Tárdeo divisions.

In the rise, which took place later, for the week ending 30th June the highest mortality reported took place in the *worli* division, and it was the same the following week, but afterwards 2nd Nágpáda and Kámáthipura shewed, as a rule, the highest average mortality, but there is nothing to shew that any special agency was at work. Both these districts have shewn a high mortality for some years past, and the Health Officer has drawn repeated attention to their sanitary defects. In looking over the weekly death returns by districts there is nothing to indicate that any special outbreak was about to take place. Turning to Mándvi, which has for years past shewn a high death-rate from fever, there is nothing in the weekly returns to shew cause for alarm till the week ending 28th July, when the total mortality was 39 (or an average annual rate of 54·37 per 1,000) and of these 8 were ascribed to fever, but next week the total mortality falls. For the week ending 25th August, however, there is an increase in the fever death and total mortality, and this continues for the next two weeks, followed by a slight decrease in the next week, but for the week ending 22nd September there is a very serious increase from fever and in the total mortality, and the existence of plague was diagnosed and confirmed shortly after. It appears that the poison when first introduced into a place spreads slowly ; but after a careful perusal of the figures supplied I am unable to state in what division the disease originated, or at what time, and it is quite possible it may have been in more than one division, but gathered strength and developed itself first in Mándvi. It is doubtful if meteorological conditions affect the incidence and spread of plague. As regards meteorological conditions in Bombay, Surgeon Lieutenant-Colonel Weir, the Health Officer, states that the mean annual temperature of the year was 80·7, the second highest on record for the past 51 years. The total fall of rain amounted to 87·6 inches, being 15 inches above the average, but the distribution of the rainfall was abnormal. " The rainfall in June was 28 inches, or 8 inches above the average, and in July the rain- " fall amounted to 36·4 inches, or 11·7 inches over the average. In August the rainfall " amounted to 20·8 inches, giving an excess of 7½ inches over the average. In September " only 1·6 inches of rain fell, being 10 inches lower than the average. This is the most " abnormal month of an abnormal year yet recorded (even in the famine years of 1876-77 " the September rainfall was not less than 4 inches), and an abnormal September was " followed by an abnormal October, dry and warm."

Ahmedabad.—Soon after plague was declared in Bombay the people began to leave for non-infected districts. The mofussil municipalities having been warned, those upon the line of rail did what was possible to keep out the disease by instituting a medical inspection of passengers arriving from Bombay, and this was attended with some measure of success ; but owing, however, to lack of legal compulsory powers, the infection could not long be kept out. The first imported case was at Ahmedabad. A Musalman working in Mándvi Bandar gave a history of fever with slight glandular enlargement beginning on 18th September, 1896. He left for Ahmedabad, arriving 25th September, and lived in the Makeriwád lane, and was under the treatment of a local practitioner for eight days, till on 3rd October he was seen by Assistant-Surgeon Gándhi, and next day by the Health Officer as well, who both considered and treated it as a plague case. The Civil Surgeon also saw the case. No connection could be traced between this and the next two cases. The patient survived. The second case was that of a Márvádi who was a loader and cart-driver working on the Ahmedabad Railway Station goods yard. He had not been away. He left work on 28th September on account of fever, was seen by Dr. Gándhi on 3rd October, and died the same day. He was acquainted with No. 3. The third case occurred in a Bania clerk, who was formerly in the service of the same master as No. 2. He had been to Wadhwan, returned on 17th September, loitered about the railway station goods yard till 24th, searching for employment. Got employment on the 26th September. Taken to Assistant-Surgeon Gandhi's dispensary on 3rd October, died on 5th. He was acquainted with No. 2. The Health Officer, Ahmedabad City, made the most careful enquiry but failed to trace any connection between the first and the next two cases, and was inclined to ascribe it to handling infected grain or goods from Bombay, but up to the close of the year no other local cases were detected. The measures recommended to the Collector were the inspection at the railway station and removal of those affected to an isolated hospital. Those healthy to be allowed to depart after disinfection, and after taking their names and addresses. In the town in the case of chawls and tenement houses,

removal of the sick was recommended, and the thorough and efficient cleaning not only of the infected room but of the whole house, the burning of infected bedding used and all rags and rubbish, and the opening up of the whole place to fresh air. The Municipality in consultation with Surgeon-Lieut.-Colonel Bartholomeusz, the Civil Surgeon, and Mr. Gibb, the Collector, engaged a staff to examine passengers from Bombay and remove the sick to the isolation hospital ; the goods in the yard were disinfected, and also what had been lately carted away, wherever possible, and arrangements made with the railway authorities to disinfect as far as possible goods and passengers' luggage at the railway station. The city was also cleaned. The houses of patients 1 and 3 were disinfected, and that of No. 2, being a hut, was burnt. After this 9 cases were detected at the railway station in October, none in November, and 38 in December, but no more local cases occurred up to the close of the year. Out of the total of 50 cases 26 deaths were reported.

Poona.—The next place from which imported cases were reported was Poona, on the 2nd October. Since 30th September two medical men with four assistants had been posted at the railway station by the Municipal authorities. Mr. Plunket, C.I.E., the Chairman of the Poona Suburban Municipality, making the arrangements and looking to the sanitary condition of the suburban limits and the prevention of overcrowding. During October four cases were detected, in November one case, and in December 43 cases. Four cases were also detected in the city and one in the cantonment. In all, 53 cases and 39 deaths were reported to the end of the year, all cases being imported. The cases were at first sent to a shed in the compound of the Sassoon Hospital, which is in the limits of the Poona Suburban Municipality, but as more accommodation was required a regular camp hospital was laid out in an open space near the hospital in December, and the cases treated there. There was a great deal of difficulty in persuading relations to allow of the sick being taken to the isolation hospital, as there was no compulsory law at the time, and in some instances the sick were taken away.

Thána, Kalyán, Dhulia, and Bándra.—After appearing in Poona, a single case of plague was detected in Thána town, 20 miles from Bombay, on the line of rail, on the 8th October, and on the same date in Kalyán town, ten miles further on, and seven days later on in Dhulia town in Khándesh. On the 26th October it was first reported in Bándra, which is really a suburb of Bombay—a town on the north-west exit from the city. Isolation and other measures were advised, but the Municipality moved slowly, and the people themselves opposed all measures of removal, and so the plague progressed. Bándra being a place noted for the number of pigs allowed to wander freely about, a caution was sent that, if any cases of sickness occurred amongst pigs, all straying were to be driven outside the town and destroyed, but information was later received that there was no cause for alarm as regards pigs, as they continued healthy. It has been stated that pigs do suffer from a disease similar to plague, but no observations made in this country have as yet come to hand.

Surgeon-Major Anderson, the Deputy Sanitary Commissioner, Western Registration District, writes that the first two important cases did not appear or spread the disease, as when it became local the parts of the town affected were not those in which these two died. The first case reported was that of a Mhár who came from Bombay on the 26th October, and the second case occurred on 24th November. Then on 3rd December it appeared in two different parts of the town ; in one case (the third) six cases occurred in the house at intervals, and dead rats had been found a week previously to the first case, and in the second case two deaths occurred, but no dead rats found. The fifth case was at a distance from the third case, but had been employed there, and in his house also dead rats were found. Subsequently the disease developed around the house of No. 3 and spread.

Escape of Kurla from the plague.—Kurla, which is situated on the north-east exit from Bombay, escaped local infection up to the end of the year.

A table is appended shewing the progress of the disease in the mofussil, but the figures shewing the attacks and deaths must not be accepted as correct, as there is little doubt that there was a great deal of concealment of cases, and many plague deaths were entered under other heads.

Karáchi.—In Sind, Karáchi was the first place affected, and the first case was reported on the 10th December, but though Surgeon-Captain Arnim, D.P.H., the Deputy Sanitary Commissioner, Sind Registration District, who was in Karáchi at the time, instituted minute and careful enquiries regarding the origin of the first two cases brought to notice, his enquiries failed entirely to trace the disease to any source outside Karáchi. Karáchi defended itself against Bombay by quarantine rules, but in spite of this there can be little doubt that the infection was imported from Bombay. The municipality were advised to

put in force the usual measures of isolation and removal of the sick and the removal of the healthy from infected houses to camps, the cleansing and opening up of the infected houses to light and air, and were also recommended to divide up the infected area into such sub-divisions as could easily be supervised, and to offer a fee for notification. The Municipality acted with promptitude, the Deputy Sanitary Commissioner, Sind Registration District, reporting that "the Municipality are taking matters in hand in a way that reflects great "credit on them," and issued a set of rules in the spirit of the above recommendations, but unfortunately the compulsory powers of segregation were not at once granted. By the close of the year 63 cases with 59 deaths had been reported, but this does not represent the real amount of the disease as great concealment was practised.

The first sanitary point in connexion with plague is to prevent its introduction into a place. When it comes in unsuspected, as it did into Bombay, the only measures are to take precautions that no further importation of infected persons and their belongings are allowed, and to try and localize the outbreak, which can be done, I think, if set about in a vigorous way and early. When, however, it is known to exist in a place, what are the measures to be taken by persons and places free from the disease? It is quite clear that without very autocratic powers not much good can be done in India to keep it out. The first thing then for a town desiring to protect itself is to obtain powers and to examine all people arriving. Those clearly sick are, of course, to be sent to an isolation hospital, but the difficulty arises in the case of those not sick, but who have come from an infected locality. In England, of course, disinfection takes place, the names and addresses are taken, and the local medical officers of health informed; if going beyond the particular town the medical officer of health of the locality is informed by telegraph. There are a number of reliable medical officers of health with comparatively small areas to keep watch over the people introduced into the locality, but in India where there is not a medical health officer for 10,000 square miles, and where if names and addresses are taken, they are by no means to be relied on, the problem is very difficult. In the case of large towns, I am in favour of camps of observation. All persons not sick, but coming or suspected to come from an infected area, should be put under observation for ten days. The persons and clothes disinfected, both on arrival and departure from camp.

In the case of persons well known to the town and not passing through, this rule might be relaxed, they and their servants might be passed, the master being held responsible for the servants, or they might be sent for inspection daily.

In villages and small towns such measures cannot be enforced, but the inhabitants themselves might prevent strangers from entering, and keep them outside the village for a ten days' period. Even if cases escaped observation such measures as indicated would prevent or greatly lessen the enormous rush of people from an infected locality and lessen the chance of spread to non-infected areas.

When the plague has seized hold of a town the only way is to divide it up into convenient areas and go through the place thoroughly by house-to-house inspection, constantly repeated without warning, for in spite of every inducement concealment of cases to a large extent will, in India, always occur. Every death also not certified by the medical officer should be treated as suspicious and the place of death inspected and disinfected.

Every one sick of the disease should be moved to an isolation hospital. The sick person is the centre of infection through the discharges. He cannot be kept isolated from friends, and when death occurs a large number of friends and relations crowd in to mourn and perform the funeral ceremonies. All this can, to a great extent, be prevented if the patient is sent to a properly equipped isolation hospital, as in case of death only the necessary relatives come to perform the last rites and the body is handed over after being disinfected. Also the other dwellers in the affected room and if necessary all in the house should be moved and the whole place thoroughly disinfected and the inhabitants not allowed to return for ten days.

Air, light and cleanliness appear to have a great effect on the disease. As far as I could gather up to the close of the year no medical men or the attendants on the sick in plague hospitals have been attacked by the disease, and this is due to the wards being well lighted and ventilated, and cleanliness insisted upon, both general and personal.

No discussion upon questions relating to importation of plague by grain, wool, hides, and other articles of commerce is entered upon, as I understand all these matters are under investigation by a Scientific Plague Research Committee now at work in Bombay.

As to how far rats are the agents by which plague is imported into a place from another at some distance is a matter difficult to decide, but that in an infected place they do carry the infection, I think there will be evidence. Many cases have been noted, especially in servants' quarters, in which were rat holes, and after dead rats had been found, though

the inmates were moved out, yet plague occurred among them ; but it is well to withhold decided opinion until the mass of evidence collecting is completed, which will give information on many important points.

As a result of this outbreak, however, more attention will be directed to sanitary measures in large towns in the way of better building laws, to try and lessen the overcrowding on space, and the regulation of water-supply and drainage.

Statement shewing the progress of Plague.

			194	2,714	2,908	2,086	

During 1896 dysentery and diarrhœa caused the deaths of 19,423 males and 16,623 females, or a total of 36,046 persons against 35,348 in 1895, and a decennial mean of 38,504. Dysentery and diarrhœa.

The Western Registration District heads the list with a ratio of 3·11 per 1,000 against 2·50 in 1895 and 2·85 the decennial mean. The Central Registration District comes next with a ratio of 2·70, the Southern Registration District 2·16, the Gujarát Registration

District 0·27 ; and the Sind Registration District 0·15. In the Presidency the rate was 1·92 against 1·88 in the previous year and a decennial mean of 2·18. All the collectorates in the Western and Gujarát Registration Districts shew higher rates than in the previous year, and four out of the five collectorates in Sind. The collectorates of Ahmednagar, Poona, Sholápur and Sátára in the Central and Bijápur and Kánara in the Southern Registration Districts alone shew lower ratios than in 1895. High ratios were recorded in Násik 4·73, Belgaum 3·88, Khándesh 3·31, Ahmednagar 3·14 ; and the lowest 0·09 in Thar and Párkar, 0·08 in Shikárpur and 0·05 in the Upper Sind Frontier, which however are higher than last year.

During the first eight months from January to August the deaths from dysentery and diarrhœa exceeded those recorded in 1895, and then at the close of the year they were less. The ten years' mean was exceeded in the months from May to August. The maximum mortality occurred in August as last year and the minimum in March. In the previous year the least mortality occurred in February. As usual, the rise in mortality takes place at the end of the hot season, increases during the rains and gradually diminishes as the cold weather sets in.

Injuries. During 1896, 3,620 males and 2,618 females or a total of 6,238 persons met with violent deaths. The mortality from these causes is more by 187 than that reported in 1895, when 6,051 deaths were recorded. Of the 6,328 deaths 2,660 occurred from drowning, 1,286 resulted from snake-bites, 678 from wounds, 206 from hanging, 130 from poisoning, 97 from attacks by wild beasts, and 1,181 from causes not specified.

Other causes. The recorded deaths from causes other than those specified number 100,112, of which 51,947 occurred among males and 48,165 among females. The total for 1895 was 97,104, so there is an increase of 3,008 under this head.

Sanitary Works—Military and Civil.

All available information under these sections has been thrown in a tabular form, and will be found in Appendices Nos. IV, V and the last four columns of Annual Form II, Appendix VII.*

It will be seen from the statement given in Appendix V that, excluding the Varungaon Municipality which has been abolished, there were 167 Municipalities in the mofussil with a population of 2,232,737 souls and an income of Rs. 55,22,074. Out of this income Rs. 25,01,157 or 45·29 were allotted for sanitary works, and out of this allotment Rs. 22,37,959 or 89·48 per cent. were spent.

Of the total expenditure Rs. 11,06,662 or 49·45 were spent on conservancy, Rs. 6,47,329 or 28·93 per cent. were spent on improvement of water-supply, Rs. 2,22,905 or 9·96 per cent. on improvement of town-sites, Rs. 54,606 or 2·44 per cent. were spent on construction and repairs of markets and slaughter-houses, Rs. 9·413 or 0·42 per cent. were spent on sanitary arrangements during fairs and festivals, and Rs. 1,97,044 or 8·80 per cent. were spent on other sanitary objects, including construction and repairs of tanks, &c.

The Bombay Village Sanitation Act of 1889 under the conditions laid down in Government Circular No. 45, dated 5th January 1895, and under a modified form sanctioned in Government Resolution No. 1090, dated 6th March 1896, has been introduced in 59 other villages during the year 1896, making a total of 222 villages since the introduction of the Act. There still remains two districts, Kánara and Upper Sind Frontier, in which the Village Sanitation Act has not yet been brought into force. In some of the villages of the Ahmedabad, Broach, Surat and Násik Collectorates, Sanitary Committees have been appointed by the Collectors in a modified form, and at Shuklatirth in Broach Táluka of the Broach Collectorate Government in their Resolution in the General Department, No. 5279, dated 2nd December 1896, sanctioned an annual grant from Provincial Revenues of Rs. 200 to the Sanitary Committee waiving all the conditions of the Circular noted above. Under the modified form Government have ruled in their Resolution No. 3187 of 2nd July 1896, General Department, that under section 11 of the Village Sanitation Act a Committee may make a variety of rules regarding the sanitation of the village, some of which need involve no expenditure and can be enforced by the Committee acting magisterially under section 14. The Committee may also be useful as a means of conveying the suggestions of the District and Sanitary officers to the villagers, and inducing their adoption by example or persuasion. The experiment tried by the Collector of Surat in the case of Olpád has proved successful. The villagers themselves

*Not reprinted.

have collected money and engaged a small staff of sweepers. Though similar experiments in another villages may not positively be rewarded with such success, the case of Olpád is encouraging. And if the Collectors, where the conditions of Circular No. 45 of 1895 are impossible, tried to apply the modified form as suggested in Government Resolution No. 1090 of 1896, in the General Department, many villages before long will come under the operation of the Act with a promise of keeping the villages clean under the orders of the Committees appointed and empowered by Collectors and sanctioned by Government.

Personal Proceedings and General Remarks.

The year 1896 has been a very unhealthy one. In the early part of the year there was an outbreak of small-pox, chiefly in the Western and Gujarát Registration Districts. Then cholera appeared in the Western, Central and Southern Registration Districts, and the mortality was largely in excess of last year. The outbreak was most severe during July and August. Upon this, towards the middle of the rains, occurred the outbreak of plague in Bombay City, and then, owing to the early cessation of the rain, widespread scarcity necessitating the opening of famine works began.

Owing to being engaged first with measures for combating the plague and later on in organising the hospital arrangements for the relief of the sick at the famine camps and visiting various famine districts, the towns visited and reported upon are not so numerous as usual.

Famine.

Owing to the insufficiency of the rainfall after July it was anticipated that there would be scarcity in several of the Deccan districts, if the fall of rain did not occur in October. As will be seen from the slight meteorological sketch given on p. 165 the rainfall did not take place. In the beginning of November arrangements were made to meet the approaching distress, and the opening of famine works was sanctioned in the districts of Násik, Poona, Sátára, Ahmednagar, Sholápur, Bijápur and Belgaum, and I was directed to take steps for the inspection of the sites for camps for the workers, to arrange for medical aid to the camps and supervise the sanitary arrangements. Accordingly the Deputy Sanitary Commissioner, Southern Registration District, was directed to inspect the camp sites in the Bijápur and Belgaum districts. The Deputy Sanitary Commissioner, Central Registration District, inspected the Ahmednagar and Sholápur Collectorates. The Deputy Sanitary Commissioner, Western Registration District, the Násik District, whilst I inspected the sites in the Poona and Sátára districts.

The sites chosen for camps were generally approved of and the places for hospitals and trench latrines fixed, and the following sanitary recommendations were made :—Workers were not to be allowed to put up their own shelters where they liked. Even if hutting materials were not available, the lines for a camp were to be marked out and spaces allotted to the workers on which to put up their own temporary shelters if they chose.

Camps for 1,000 workers were laid out mostly on the following plan:—Huts 6 ft. × 6 ft. facing north and south in lines of five. North of the huts was a space of 50 ft. to the next line of huts, and on east and west a roadway of 20 ft. The huts might be closed up on the south side, but were to be left open on the north to facilitate inspection. The hospital buildings were as a rule on the south-east or north-west of the camp, and the latrine trenches to the east or north-east. The hospital was to consist of a hut of two rooms, one for the Medical Officer and the other for the dispensary and drug-store. A general ward for 30 patients divided for males and females, an ulcer ward for 12 cases, diarrhœa and dysentery ward for 12 cases, and further east a small-pox ward for 6 cases and a cholera ward for 10 cases.

An enclosure with lean-to shelters was recommended for all non-working children, who could walk, to stay in during the working hours, so that they should not interfere with the workers and foul the working camp. Also the dwelling camp was to be entirely cleared of all people during the working hours, except the guards and those who had to clean the camp. This was very necessary, as old people and children used to occupy the huts and defilement was going on all day.

In order to preserve the purity of the water-supply of camps, which was mostly from wells or running streams, it was recommended that the whole supply should be taken from wells which, if not already existing, could be roughly sunk in the beds of streams, and then a bhisti service organised to draw the water in clean vessels and deliver it into large receptacles near the camp, from which it could be served out to workers as required. Except these

bhistis, no other workers were to be allowed near the wells, which were, from time to time as occasion required and when cholera prevailed, disinfected with permanganate of potash.

Great difficulty was experienced in getting the workers to use the trench latrines, and it was only on the large camps over which the supervision was very strict that the orders could be regularly enforced.

As it was soon perceived that the numbers of workers and of camps would be largest in the Ahmednagar, Sholápur and Bijápur districts, the services of three Commissioned Medical Officers were applied for with the view of posting one to each collectorate as a District Medical Officer, and at first Surgeon-Captain Lloyd Jones was posted to Ahmednagar, Surgeon-Lieutenant Standage to Sholápur, and Surgeon-Captain T. B. Smith to Bijápur.

Regarding the supply of Assistant Surgeons and Hospital Assistants to act as Medical Officers at relief camp hospitals, the demand was more than could be supplied owing to the prevalence of plague. The Surgeon-General with the Government of Bombay supplied as many as were available, and on his representation Government were pleased to sanction the employment of temporary Hospital Assistants for famine duty, and later on, as large and more permanent camps were formed, the engagement of temporary Assistant Surgeons. Even with this there were not enough men, but by placing the medical officers centrally and directing them to visit twice a week the relief camps within a certain distance, sometimes 8 to 10 miles off, and by utilizing, with the permission of the Surgeon-General, the services of the medical men in charge of dispensaries, medical supervision and aid was afforded to a large number of camps and workers. Fortunately also the health of the workers was to the close of the year extremely good. There was no cholera and very little small-pox, but the medical officers did very hard work in constantly inspecting and reporting upon the sanitary condition of the camps, and the health of the workers, examining the quality of the food supply, and also treating the out-patient ailments, which were numerous and consisted for the most part of conjunctivitis, guinea worm, injuries of a trifling nature, and occasional attacks of fever and diarrhœa. I have great pleasure in bringing to the notice of Government the meritorious conduct of the great majority of these officers and the hard work they have cheerfully done, and I trust when the Famine Code is next amended that a definite scale of travelling allowance, and permanent advance for ordinary hospital expenditure will be laid down, as the want of definite ruling has caused a large amount of correspondence and a good deal of hardship and irritation. The allowance granted in ordinary times is quite insufficient in areas where distress is prevalent. The Dispensary medical officers who were ordered to attend famine relief camps, in addition to their own duties, should not be forgotten either.

The medical officers placed on famine duty were at first distributed to Bijápur 8, Sholápur 8, Ahmednagar 4, Sátára 4, Poona 4, Belgaum 3, and Násik 1. According to scale laid down each medical officer was supplied with medicines and instruments and appliances, and a set of furniture. Diet scales and a list of hospital comforts and petty supplies allowed were issued, and a small hospital establishment was also sanctioned.

The condition of weavers was carefully enquired into as it was considered that they would not be able to stand the different kind of work and the scale of food allowed, and it was found as the result of constant enquiry that, with the exception of the old people, the work they did and the food they got did not cause any deterioration.

A scale for the diet of confined women and recommendations regarding nursing mothers and infants were also made.

The numbers on famine relief works in each district affected are given below, and then the death rates for each district from July to the end of the year, contrasted with the ten-year mean. Up to the end of the year no one was reported to have died of starvation.

Statement shewing the number of workers in Famine Relief Camps at the close of 1896.

District.	Population according to Census of 1891.	Number of workers.
Bijápur	796,286	229,895
Sholápur	750,255	277,971
Ahmednagar	887,656	97,333

Sanitary Board.—During the year the Sanitary Board gave advice regarding the water-supply schemes of Surat and Rander, Malegaon, Islampur, and submitted a report on the Sátára water supply. They also advised on the sewage farm at Ahmedabad, on the Motlibai and Petit Hospitals, Bombay, the Lunatic Asylum and the Sassoon Hospital at Poona, and the Sukkur drainage works. The Board also gave advice on a number of miscellaneous projects.

ABSTRACT OF REPORT OF THE HEALTH OFFICER OF THE PORT OF BOMBAY FOR THE YEAR ENDING 31ST DECEMBER 1896.

The following table gives a summary of the shipping and health of the port of Bombay and of the work in connection therewith for the year ending 31st December 1896 :—

Vessels including Native Craft.	Number.	Number of Passengers as far as is known.	Number of Vessels Inspected.	Number of Persons including Crew on Vessels Inspected.	Number of Vessels Disinfected.	Number of Persons Vaccinated.	Diseases and Number of Cases of Each.						
							Bubonic Plague.	Cholera.	Small-pox.	Measles.	Scarlatina.	Chicken-pox.	Enteric Fever.
Entered	47,948	423,966	22	21,654	14	601	2	1	5	5	3	5	1
Left	39,695	459,939	503	90,624	—	—	—	—	—	—	—	—	—
		Including Harbour Population.											
In harbour during the year.	1,310	22,142	45	—	45	176	—	37	7	4	—	1	—
Total ...	88,953	906,047	570	112,278	59	777	2	38	12	9	3	6	1
1895 ...	90,317	901,370	572	100,016	19	879	—	22	7	21	2	5	1

In the above table the "number of crew" on board ships entering the harbour is not shewn, as no record is kept. The discrepancy between "arrivals" and "departures" is explained by the fact of boats arriving with grass, wood, and other local cargo, from across the harbour being registered as "arrivals," without being registered as "departures" when they again leave for similar cargo.

The following table furnishes further particulars regarding vessels which entered the port during the year :—

Year.	Total Number of Steamers and square-rigged Vessels which entered Bombay Harbour from Ports other than Indian Ports.	Number of Passengers.	Total Number of Native Sailing Craft which entered Bombay Harbour from Ports other than Indian Ports.	Number of Passengers.	Total Number of Steamers and square-rigged Vessels which entered Bombay Harbour from Indian Ports.	Number of Passengers.	Total Number of Native Sailing Craft which entered Bombay Harbour from Indian Ports.	Number of Passengers.
a	*b*	*c*	*d*	*e*	*f*	*g*	*h*	*i*
1896	684	43,527	235	1,886	1,344	378,553	45,685	Unknown
1895	758	38,745	334	1,856	1,248	419,882	45,870	Do.

There is no record kept of the crews of incoming vessels, and, in the case of native craft, none of either crews or passengers ; hence the total number of persons who arrived

by the vessels shewn in the above table cannot be given. Of the 423,966 passengers shewn, 15,598 were troops, 9,892 pilgrims from the Hedjaz, and the remaining 398,476 chiefly passengers from ports near Bombay.

The following table shews the number of ships which had infectious disease on board on or before entering the harbour :—

Class of Vessels.	Number of Ships.	Total Number of Crew and Passengers.	Diseases and Number of Cases of Each.							Number of Persons Vaccinated.
			Bubonic Plague.	Cholera.	Small-pox.	Measles.	Scarlatina.	Chicken-pox.	Enteric Fever.	
1. Troopships	4	5,476	—	—	—	2	2	4	1	—
2. Pilgrim ships	3	2,374	—	—	4	—	—	—	—	546
3. Other vessels	7	1,254	2	1	1	3	1	1	—	55
Total	14	9,104	2	1	5	5	3	5	1	601
1895	9	5,318	—	11	3	21	1	2	1	864

Vessels which became infected while in port are not shewn in the above table but are given in table on page 178.

The cases of measles, scarlatina, and chicken-pox, referred to in the foregoing table as having occurred on board the Indian Troop Service Transports, were landed and isolated in the military cantonment at Colába. The small-pox cases were removed to hospital on shore and those unprotected amongst the crew and passengers were vaccinated before they were allowed to land. During the year under report 601 persons were vaccinated on board the small-pox infected ships which are mentioned in the above table. Two deaths from plague were landed by a Shepherd's coasting boat which was put back from sea a day after her departure from Bombay on account of cyclonic weather. One death from cholera occurred during a voyage of a Shepherd's steamer from Marmagoa to Bombay. All these ships were thoroughly disinfected on their arrival at Bombay before pratique was granted them.

No vessels arrived during the year with suspicious cargo, infected cattle, or glandered horses.

The following table shews the number of vessels of all kinds which sailed from the port of Bombay during the year :—

Year.	Total Number of Steamers and square-rigged Vessels which left Bombay Harbour for Ports other than Indian Ports.	Number of Passengers.	Total Number of Native Sailing Craft which left Bombay Harbour for Ports other than Indian Ports.	Number of Passengers.	Total Number of Steamers and square rigged Vessels which left Bombay Harbour for Indian Ports.	Number of Passengers.	Total Number of Native Sailing Craft which left Bombay Harbour for Indian Ports.	Number of Passengers.

The following table furnishes details of outward vessels of all kinds, bound for Quarantine Ports, which were inspected during the year and granted B Form Bill of Health. By Quarantine Ports are meant ports of Mauritius, Aden, Red Sea, Europe

viâ Canal and Persian Gulf, vessels for which, with their crews and passengers, are inspected on the dates of sailing before Bills of Health are given. This table includes 19 pilgrim ships bound for Jeddah.

Names of ports to which sailed.	Number of vessels.	Number of Tonnage (net).	Number of individuals comprising crews.	Number of passengers.	Total of crews and passengers.
I.—Square-rigged Vessels and Steamers.					
Europe, *viâ* the Suez Canal ...	217	527,799·51	18,915	8,138	27,053

1895	540	794,588·02	35,367	45,509	80,876

In addition to the above, Form C Bill of Health was issued to 648 vessels. This form is usually taken by vessels bound for Indian, Chinese and East African Ports, where quarantine restrictions are mild, or are only enforced against arrivals from infected ports. Thus the total number of Bills of Health issued during the year was 1,151 against 1,206 in the year 1895 and 1,177 in the year 1894.

The remaining 38,544 vessels did not take Bills of Health, being either only coasting craft or Shepherd and Company's ferry steamers.

Attached to each Bill of Health was a necrological certificate shewing the number of deaths from plague, yellow fever and cholera in the Town of Bombay during the week preceding that in which each vessel sailed, as these certificates have to be produced in certain ports. All Bills of Health issued up to the 29th of September 1896 were clean ones. On that date, however, as the Medical Board reported that there had been several cases of bubonoid fever, the necrological certificate, the end of which usually reads "that "the public health of the environs was good," was made to read "that the public health of "the environs was poor, several cases of bubonoid fever having occurred during the past "month in the Mandvi District," until the 8th of October 1896, when bubonic plague was declared to be mildly prevalent in the Mandvi District, and Bills of Health were modified

as follows, viz. :—Form B, the end of which usually reads, " It is certified that the Town " and Port of Bombay are at present free from epidemic cholera, plague, yellow fever, and " all other dangerous epidemic disease " was made to read " It is certified that the Town " and Port of Bombay are at present free from epidemic cholera, yellow fever and all other " dangerous epidemic disease, except bubonic plague which exists in a mildly epidemic " form in the Mandvi district," and the necrological certificate further modified and made to read " that the public health of the environs was poor on account of the presence of " bubonic plague in a mildly epidemic form in the Mandvi District." From the 10th of December 1896, until the end of the year, as the plague had extended into other districts and assumed an epidemic form, the bills of health were further modified as follows :—viz. Form B to read : " It is further certified that the Town and Port of Bombay are at present " free from epidemic cholera, yellow fever and all other dangerous epidemic disease except " bubonic plague which exists in an epidemic form " ; and Form C to read : " This is to " certify that there is no epidemic disease prevailing in the city and suburbs of Bombay " except bubonic plague which exists in an epidemic form."

There were no cases of infectious disease dangerous to life found, on inspection of any vessel prior to departure.

The sanitary condition of outward-bound vessels was, as a rule, satisfactory. The principal defects noticed were much the same as in other years, viz. :—

(*a*) Overcrowding of crews' quarters.
(*b*) Faulty construction of crews' quarters.
(*c*) Want of proper accommodation for deck passengers on long voyages.
(*d*) Foul bilges in native craft.

As in previous years, overcrowding of crews' quarters was chiefly observed among the regular liners so constructed as to carry as many passengers as possible, and is occasioned by vessels often having to take home an extra crew to man some other vessel of the same line. Such extra crew has to be provided with accommodation, and endeavours to accommodate its members with their boxes, in quarters already nearly full, leads to overcrowding. There has been a tendency among Commanders of vessels, which do not belong to the regular passenger liners, to provide temporary accommodation for such extra crews, when possible, and this was, in most cases, done in consultation with the Health Officer of the Port during the year ; but this procedure is not generally feasible in the case of vessels constructed to carry passengers in every available corner, and with very few exceptions, was not attempted, those responsible generally urging, by way of explanation, the fact that the permanent quarters were much in excess of the minimum space required by law, and that the extra hands accommodated did not cause such minimum to be reduced. However true that may be theoretically, in practice it is attended with much disadvantage as necessity arises for erecting hammocks, which with men's kit and boxes not only do diminish the minimum space per head required by law, but also render it very difficult to keep quarters clean and sanitary. These remarks apply to those vessels only which were inspected, and it is highly probable that they would also apply to a large number of outgoing vessels which do not undergo inspection by the Health Officer of the Port. In the case of one vessel, a pilgrim liner, notice was given to the owners that the Health Officer of the Port would feel justified in withholding a bill of health unless the crews' quarters were improved.

A large number of iron-decked vessels were inspected during the year, and found to have no wooden sheathing on the deck over the crews' quarters or within these quarters. The number of iron-decked vessels is increasing, but the new ones are bound by law to have their crews' quarters sheathed within and without ; this law does not apply to the old ones unless complaints regarding them be made and sustained. In many cases wooden planks have been placed under the decks over the bunks, but these are of very questionable utility, and harbour vermin. Cases of this were only observed during the year upon several buggalows, which were granted Form B bill of health. Upon steamers it was not observed to any extent, but this remark only applies to those steamers which were inspected. Many vessels of all kinds proceed on long voyages which do not have to undergo inspection, and it is possible that some of these may require better accommodation for deck passengers than they possess.

In only a very small number of instances steps had to be taken on account of dirty bilges in native craft, as Nácodas have been becoming more careful. In the case of one buggalow, in which the bilge was unusually foul, a specimen was taken and subjected to quantitative bacteriological examination, and found to contain no less than 5,400,000 microbes to one cubic centimetre.

Infectious Disease on Vessels in the Harbour.—The following table includes all steamers, square-rigged vessels and native craft, which became infected while lying in port, but not those given in the table on page 175, which became infected while at sea :—

Months.*	STEAMERS.									BUGGALOWS, TONIES, PROWS, STEAM LAUNCHES, &C.										TOTAL NUMBER OF CASES OF INFECTIOUS DISEASE IN THE BOMBAY HARBOUR.

* No cases of infectious disease occurred in the Bombay Harbour during October, November, and December.

Out of a harbour population estimated at 22,142 there were 37 cases of cholera, 22 of which proved fatal. These cases were distributed as follows :—

1 Steamer ... ... 1 case.
33 Prows, Tonies, Dingies, Buttelas, &c. (native craft) ... ... 36 cases.

Of other diseases the following are the details :—Out of the seven cases of small-pox shewn in the foregoing table, three occurred on board of three of Her Majesty's Indian Marine Ships, and the remaining four on board of P. & O. vessels and other steamers which were in the harbour at the time. Out of the four cases of measles, two occurred on board Her Majesty's Ship "*Warren Hastings*," and one on board Her Majesty's Ship "*Maydala*," and one on a British India Ship. The case of chicken-pox was reported to have been removed to the Saint George's Hospital from one of the Indian Marine Ships. All these vessels were disinfected as thoroughly as possible. In connection with seven cases of small-pox, 176 persons were vaccinated.

The following table shews reported cases of cholera on native craft of all kinds in the port during the past 12 years. It is possible that the apparent high death-rate is due to the fact that mild cases ending in recovery are not reported. It was observed that the fatal cases pursued a very rapid course, but this is probably due to inaccurate and unreliable reports :—

Years.	Cases.	Deaths.	Percentage of deaths amongst those attacked.	Years.	Cases.	Deaths.	Percentage of deaths amongst those attacked.
1885	30	26	86	1892	12	12	100

1889	23	21	91	1896	36	22	61
1890	3	2	66				
1891	5	5	100	Total ...	202	162	80

Disinfection of Ships and General Health of the Shipping.—Fifty-nine vessels of various kinds were disinfected during the year, under the supervision of the Water Police, according to directions given by the Port Health Officer. The Naval Authorities dealt with the disinfection of Her Majesty's Marine and Indian Troopships on which infectious disease occurred. No opposition was raised by Commanders and owners.

The health of the harbour population was satisfactory during the year. The following details shew the distribution of the admissions into the various hospitals:—The Saint George's Hospital during that time admitted 504 Europeans, of whom 12 died; whilst the Jamsetji Jijibhoy Hospital admitted 86 natives, of whom 9 died; and the Gokuldas Tejpal Hospital 120 natives, of whom 8 died. The total number of admissions into these hospitals were 710 and the number of deaths 29.

Sixteen inquests were held by the Coroner of Bombay during the year on bodies of persons who died from the effects of accidents while at work on board ships in docks and at bandar or in the harbour. There were no cases of bilge-poisoning reported during the year.

Quarantine against Bombay.—The following table shews the action taken in other ports during the year against Bombay on account of the prevalence of bubonic plague :—

Authority or Government Resolution. No.	Date.	Name of Port at which Quarantine was imposed.	Remarks.
4358	3rd October 1896 ...	Ceylon	Quarantine on vessels until inspected.
4395	5th October 1896 ...	Alexandria	Application of plague rules in force since 13th June 1894 to arrivals from Bombay.
4431	7th October 1896 ...	Ceylon	Strict quarantine of vessels from Bombay.
4434	Do. ...	Bussorah	21 days' quarantine.
4435	Do. ...	Aden, Perim and Somáli Coast.	Application of plague rules similar to those in Bombay Notification No. 2780 of 26th July 1894, to arrivals from Bombay.
4540	13th October 1896 ...	Turkish Ports ...	10 days' quarantine.
4570	14th October 1896 ...	Spain	Quarantine in Spain on arrivals from Bombay after 10th September 1896.
4557	Do. ...	Ceylon	8 days' quarantine on arrivals from Bombay after 10th September 1896.
4585	16th October 1896 ...	Persian Authorities ...	Imposing quarantine on arrivals from Bombay.
4607	17th October 1896 ...	Goa	5 days' quarantine against passengers from Bombay arriving by rail or sea.
4629	20th October 1896 ...	Madras, Calcutta and Rangoon.	Issue of quarantine rules against Bombay similar to those of 26th July 1894.
4673	21st October 1896 ...	Calcutta	8 days. Vessels on which no disease has occurred exempted, provided they carry Medical Officer or have been granted pratique at Colombo and other intermediate ports.
4729	24th October 1896 ...	Goa	5 days' quarantine against passenges by steamers from the date of their arrival from Bombay.
4774	27th October 1896 ...	Alexandria	All ships coming from plague-infected ports for Suakim even shewing clean bills of health during voyage must disinfect first at Moses Wells.
4852	30th October 1896 ...	Dutch Colonies ...	Enforcement of usual quarantine rules against arrivals from Bombay.
4885	3rd November 1896 ...	Bushire	8 days dating from departure from East Indian Port.
4916	7th November 1896 ...	Singapore	Bombay declared infected from 6th November 1896.
5105	21st November 1896...	Do.	Vessels from Bombay *via* Colombo admitted free if they bring a clean bill of health from the latter port, while vessels arriving direct will be admitted to pratique if no cases of plague therefrom has occurred on board during the eight days preceding their arrival.

No quarantine was imposed during the year at Suez against arrivals from Bombay. The following table shews the number of days during which quarantine was in force at Suez against arrivals from Bombay since the year 1884, with the number of deaths from cholera in Bombay each month :—

Year	Number of days at Suez during which Quarantine was in force against Bombay.	Total Number of Cholera Deaths in Bombay City for the Year.	Number of Cholera Deaths in Bombay City for each Month.												Remarks.
			January.	February.	March.	April.	May.	June	July.	August.	September.	October.	November.	December.

1896	Nil	490	8	2	17	43	83	54	82	143	47	7	2	2	

Red Sea Pilgrim Traffic.—The new Pilgrim Act of 1895 came into force on the 6th of October 1896, and those vessels which sailed after that date, with the exception of the S.S. "*Naderi*," are considered pilgrim ships under that Act, while all those shewn as having sailed before that date were considered pilgrim ships under the Native Passenger Ships Act.

Nineteen pilgrim ships sailed for Jeddah during the year with 14,167 pilgrims and 311 passengers for other ports. Under the Pilgrim Act of 1895 it is necessary that each pilgrim should have six square feet of free upper deck space in addition to 12 square feet on the 'tween or 16 square feet if travelling on the orlop deck. It is also necessary that exclusive of side scuttles and hatches, each pilgrim on the 'tween-decks should be provided with five square inches of ventilation, and on the orlop deck with ten square inches. None of those pilgrim vessels which left during the year under the new Act carried any pilgrims or passengers upon orlop decks.

The pilgrims as usual included all classes of Indian and Central Asian Mahomedans. Among them was observed the usual number of aged, lame, blind and very young. On the whole they were a fairly healthy lot. Stowaways were not numerous during the year.

Out of a total number of 14,167 pilgrims who sailed, there were 271 admissions into hospital on board and 49 deaths. The average duration of the voyages to Jeddah, not including the period of quarantine imposed at Camaran, was 14 days.

The medical inspection of all pilgrim ships was carried out in the Prince's Dock during the year and much valuable assistance was rendered by the officials of the Preventive Service under Messrs. Walsh and Blunt and by the Police under Mr. Lee-Smith, especially after the new Act came into force, when the inspections were tedious and of a complicated nature.

The usual ten days' quarantine was imposed upon all pilgrim-ships arriving just prior to the Haj (which in 1896 was on the 23rd May) at Camaran which was opened for the reception of pilgrims on the 18th of December 1895.

In addition to the above, fourteen vessels arrived from Jeddah with small batches of pilgrims and other passengers during the year.

The returning vessels were of the same class as those which made the outward voyages. Nineteen vessels embarked a total of 11,133 souls at Jeddah and Camaran. There were 365 admissions into hospital and 136 deaths.

Owing to small-pox existing on three vessels on arrival in Bombay, 546 pilgrims were vaccinated.

The difference between those who left for and those who returned from Arabia amounts to about 15 per cent. against 28 per cent. last year and an average of 33 per cent. in previous years.

Sanitary state of the harbour and foreshore.—Referring to Surgeon-Major MacCartie's Annual Report of 1895, he mentions eight bandars in which grave sanitary defects were observed : —

(1) *Victoria Bandar.*—He here stated that the 30-seat latrine was not sufficient ; there are now in addition 1 with 20 seats, 2 with 15 seats, 3 with 6 seats, 2 with 3 seats and 1 with 1 seat ; and the sanitary condition is much improved.

(2) *Mill Frontage from Jamsetji to Arthur Bandars.*—There is still insufficiency of latrine accommodation here and consequent fouling of the foreshore.

(3) *Arthur Basin.*—The nuisance caused by the discharge of the Tramway Company's drain has now ceased to exist.

(4) As pointed out last year by Surgeon-Major Crimmin, Mody Bay South Reclamation has ceased to be a nuisance as it has been taken up for a bulk oil installation.

(5) *Frere Bandar.*—There is still insufficient latrine accommodation and consequent much fouling of the foreshore where large gangs of coolies are employed.

(6) *Malet Bandar.*—There has been little if any improvement here, and the smell at low tide is most offensive. More latrine and urinal accommodation is urgently wanted.

(7) *Mazgaon Basin.*—The condition of this basin is much the same now as it was in 1895, and it is often very offensive at low water.

(8) *Kasára Basin.*—The drain is still above low-water mark, and the basin is in consequence still foul, and, as remarked by Surgeon-Major Crimmin last year, will probably remain so until the drain is included in the proposed Mázgaon Drainage System, or the basin filled in.

In addition to the above, the basin at Mody Bay North is offensive at low water, and it is reported that a large number of rats died here in October. There is also a large drain which discharges off Carnac Bandar, the smell from which is intolerable, and I found the water in the vicinity on bacteriological examination to contain 900,000 microbes per cubic centimetre.

Excepting the above remarks there has been a decided improvement in the state of the foreshore during the past few years owing chiefly to the exertions of the Port Trustees.

I conducted a large series of bacteriological experiments during the year for the quantitative examination of harbour water, and it is of interest to note that after high tide the current from the Thána river so effectually clears the foreshore that no trace whatever of any contamination is found in the middle of the harbour ; for example, although 900,000 microbes per cubic centimetre were found in Carnac Bandar, 10,000 near Apollo Bandar, and 14,000 near the Docks, in a line running from South Karanja to Sassoon Dock, a large number of specimens of water were collected at regular intervals of distance, during middle ebb-tide, and not one of them was found to contain more than 100 microbes per cubic centimetre, the practical significance of which will be understood when it is remembered that fresh water which does not contain more than 100 microbes per cubic centimetre is fit for drinking.

ABSTRACT OF REPORT OF THE CALCUTTA MUNICIPALITY FOR 1896-97.

(*Mr. R. Bright, Acting-Chairman.*)

Turning now to the history of the work done during the past year, the Commissioners consider that the record must be allowed to be satisfactory. The year, if it were memorable for nothing else, would be most noteworthy in the history of the town because it has witnessed the inception and commencement of sanitary works of the highest importance. These works are connected with—

(1) Unfiltered water supply.
(2) Drainage and sewerage.

As regards the former the scheme includes—

(*a*) Remodelling and extending the arrangements for supplying unfiltered water in the Town Area.
(*b*) Supplying unfiltered water to the Suburbs.

As regards the second series of works the scheme includes—

(*a*) Works necessary for the improvement of outfall of the Town system of sewerage.
(*b*) Drainage and sewerage of the Suburbs.

Extension of unfiltered water supply.—As regards the works which are designed for the improvement and extension of the unfiltered water-supply, it is hardly possible to exaggerate their importance. In a flat country like that upon which Calcutta is built, the sewers have, of necessity, to be laid with a fall which is quite insufficient for self-cleansing, and it is only by flushing that they can be kept in a state of proper cleanliness, and the sewage properly diluted. The present supply of unfiltered water, amounting to 5,625,163 gallons per diem, is insufficient even for street-watering, and proper flushing of the sewers is out of the question. Moreover, owing to the want of a proper supply of unfiltered water, the extension of the sewer system has been seriously impeded, and connections with private privies have been impossible. The work now undertaken by the Corporation will, it is hoped, not only greatly improve the state and efficiency of the existing sewers, but will also render possible connections of private privies with the sewers and thus in time largely diminish the night-soil establishment. In all ways and from all points of view, the Commissioners are of opinion that these works are of the highest importance for the improvement of the sanitation of the town.

The works sanctioned by the Commissioners to secure these ends were—

(1) Renovating and altering the engine-house at Mullick's Ghat.
(2) The construction of a new jetty to carry the necessary suction-pipes.
(3) The provision of engines with eight times the capacity of the present plant of 1,200 H.P.
(4) Additional mains to carry the increased supply to the principal streets of the town with the necessary arrangements to admit of the subsidiary pipes being gradually laid.

The progress made in this direction during the year has been substantial—

(1) The engine-house at Mullick's Ghat is being enlarged and altered at a cost of about Rs. 41,000.
(2) The jetty for the suction-pipes has been completed at a cost of Rs. 49,000.
(3) In April last a sum of £25,622 was sanctioned for the purchase of engines which, it is hoped, will shortly be at work.
(4) A tender of Messrs. Martin and Co., amounting to Rs. 5,52,361 for town and Rs. 4,93,514 for suburbs, for laying additional mains, has also been accepted, and 15,495 feet of these mains have been laid during the year out of a total estimated length of 3,05,400 feet.

As regards the provision of unfiltered water supply to the suburban area, it is proposed to move the plant now working at Mullick's Ghat to the river bank at Hastings and to construct an engine-house and jetty there, similar to the one at Mullick's Ghat. The land has been arranged for, contracts for shifting the engines have been entered into; in the suburbs most of the pipes have arrived, the work is being pushed on vigorously, and will, it is hoped, be finished during the current year.

Extension and improvement of the sewerage system.—Of equal or even greater importance are the works which have been commenced, with a view to improve the outfall of the

sewers of the town proper, to provide for the drainage of the Suburbs and of the area between the Canal and the Circular Road. The problem to be solved was one of great intricacy and has engaged the attention of this Corporation for several years past. The facts to be dealt with, in the case of the town area, may be thus described. The outfall for storm-water was defective, because the sewers of the town discharged into a channel of insufficient capacity, which was constantly liable to be blocked owing to the tide-levels at the outfall being too high to avoid flooding in the town, and the object of the proposed works is to provide a channel of sufficient capacity, with sufficient storage-room to hold the discharge of the sewers during the time the outfall is obstructed by the tide at a level which can have no dangerous effect in *banking* up the sewers. The capacity of the present pumping plant at Palmer's Bridge is insufficient to deal with the existing quantity of sewage, while the capacity of the present high level sewer is also too small. *A fortiori* these will be even more inadequate than they are at present, as soon as the burden of dealing with the sewage of the Suburbs is added.

To deal adequately with the sewage, larger pumps are to be fixed at Palmer's Bridge, a new high level sewer is to be constructed which will meet with a new high level sewer intended for the suburban outfall, and the combined sewage of the Town and Suburbs is to be carried in a channel lined with masonry to a new outfall some miles below the present one.

The second section of the drainage project provides for a main sewer from Watgunge on the banks of the Hooghly which will discharge at a station to be established near the Rifle-range.

The suburban outfall will be precisely similar to that now working at Palmer's Bridge.

The original plan provided for three pumping stations for the suburban main sewer, but more complete information has enabled Mr. Hughes to modify his plans, and there will now be only two pumping stations, one at the Budge-Budge Road and one at the outfall.

At the commencement of the year under report a preliminary project had been prepared by Mr. Hughes embodying his proposals. During the year surveys were made and details settled, plans and estimates were prepared and the work has been vigorously pushed on by the Commissioners ; contracts were entered into with Messrs. Martin and Co. for the storm-water and sewage outfall of the Town Proper on 10th October, 1896, and the foundation-stone of the drainage works was laid by His Honour the Lieutenant-Governor at Palmer's Bridge on the 26th November, 1896.

The contract for the section of the suburban drainage south of Tolly's Nullah was given to Messrs. Martin and Co. in October, and that for the Suburban Drainage, north of Tolly's Nullah, was given to Messrs. Burn and Co. by the General Committee on the 23rd April last. The progress of the work has been hindered by the delays inseparable from the proceedings for the acquisition of the land. As regards the town outfall works, good progress has been made in the manufacture of lime and bricks, and a considerable quantity of earth-work has been excavated, pipes have been laid for the supply of water to the labourers and rails and rolling-stocks for the tramway have arrived.

As regards the work for the sewers south of Tolly's Nullah, some progress has been made in the actual laying of the sewers.

The work for the system, north of Tolly's Nullah, was not commenced during the year under review.

As regards the project for the canal area the surveys are almost complete.

From the above facts it will be seen that these works and projects, which are of the highest importance to the sanitation of Calcutta and which involve engineering problems of great difficulty, have at last passed the stage of discussion and are on the fair way to completion.

The number of premises connected with the public sewers during the year was 448 bringing the total up to 29,588. The sewers, including 9·42 miles of bustee-sewers, now measure 209·341 miles excluding house-connections.

Simultaneously with the extension of the sewerage system to the Suburbs, there have been road projects undertaken which are of great importance to the Suburbs. The principal of these are the Badiapara Road, the Lansdowne Road extension, the high level sewer road, the improvement of the Hazra Road, the storm-water escape and sewer road, and the Kalighat Road. The suburban area will be greatly benefited by these roads, especially by the Lansdowne and Badiapara Roads, the latter of which does away with part of a very filthy quarter. Contracts for these two roads have been given out, and the work is in progress.

The new Kalighat Road has been completed during the year, and a project has been prepared for improving the Strand Road, while the extension of the Badiapara Road to Kalighat Road is under contemplation.

Turning aside from the large projects for dealing with the drainage of the Town and Suburbs, it is necessary to note that good progress has been made with the Suburban Drainage Temporary Project.

The pail and cart-depôt, at the Budge-Budge Road, has been working successfully since June, while the depôt No. 2 at Hazra Square has also been completed. All necessity for night-soil trenching at Bhatchala should be at an end, while necessity for trenching at Dhakooriah will almost cease.

Water Works.—Turning next to the Water Works Department the average daily consumption of filtered water has risen to 20,786,655 gallons, while that of unfiltered water has very slightly fallen from the figures of the previous year.

The demand for unfiltered water is far beyond the present means of supply. There has been some extension of both filtered and unfiltered pipes. Filtered water during the year was supplied to all bathing-platforms in place of an unfiltered supply.

The year's experience has brought one fact even more prominently to notice than usual. That it is impossible with the present mains, which were *constructed to carry a much smaller quantity of water*, to maintain the statutory head of pressure. These subjects are under the consideration of the Commissioners, and it is hoped that, after the supply of unfiltered water has been introduced, it may be possible to reduce the expenditure of filtered water within reasonable limits, and then to restore the head of pressure to its statutory amount.

The length of water main laid chiefly in small extensions on the distribution system during the year (filtered supply) was 1·47 miles. The total length of filtered water mains now amounts to 312·06 miles. In addition to this 5,882 feet of 3 inches and 72 feet of 2 inch-pipes have been laid to extend water-supply to Plague Hospital at Manicktollah. The number of premises connected during the year was 872. The total number of premises connected now amounts to 27,184.

The working of the C. and D. engines at Tallah caused great anxiety during the year, and a contract has been entered into with Messrs. Simpson and Co. for the supply of two Worthington pumps.

Miscellaneous.—In the other Departments too, important work has been done. The repairs to the Town Hall, which were of a most extensive character, were nearly completed by the end of the year. The question of the erection of a suitable Municipal Office was also discussed, and it was finally decided to build extensions of the existing building so as to allow of all the Departments being housed under one roof. This is a most desirable thing, and will, when completed, do much to facilitate work.

An estimate, amounting to Rs. 58,000, was sanctioned during the year for the construction of new knackery at Dhappa, which, it is hoped, will be completed during 1898-99, and which, when finished, will have the effect of doing away with the nuisance which at present undoubtedly exists.

The system of electric lighting in Harrison Road was improved at a cost of Rs. 10,600.

A most important change during the year has been the introduction of the contract system, by which large drainage and water work projects have been entrusted to responsible firms. The practice up to 1895-96 was to purchase pipes in England through an Agent and then lay them departmentally.

Health Department.—The last department which seems to call for notice in a brief summary of the history of the year is the Health Department. In this Department too there is a record of strenuous exertion.

The advent of the Plague in Bombay naturally gave rise to apprehensions that it would very probably appear in Calcutta, which is so closely connected with the city where the disease established itself.

With a view to provide against this contingency, a large temporary establishment was engaged in the cleansing of the town, a Chief Superintendent of Conservancy was appointed, and the extra expenditure thus involved resulted in an excess of Rs. 57,578 over the Budget estimate. The town generally, and the worst houses in Burra Bazaar and Jora Bagan, have had such a cleansing as they have never before received. An isolation hospital was also erected. Fortunately, the plague did not break out in the town.

The investigations which were made during the year into the sanitary condition of the town brought prominently into notice the extremely unsatisfactory state of the existing

law which regulates buildings. A Building Commission was appointed to consider the question, but their deliberations are not as yet concluded.

Health of the Town.—The birth-rate was higher than that recorded in any of the previous seven years, except 1892 and 1893. On the other hand, the mortality, while less than that of the preceding year, was in excess of the quinquennial average. Fever was prevalent to a considerable extent, and cholera prevailed with considerable virulence in March, April and May. On the other hand, the number of deaths from small-pox was exceptionally small.

ABSTRACT OF REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1896.

(*Dr. W. J. Simpson.*)

Meteorology. The variations in the atmospheric pressure during the greater part of the year were small, the lowest reading 29·501 being recorded in July, and the highest 30·059 in December. The mean daily variations of temperature were greatest from January to May and October to December, and least in August. The mean daily dew-point was highest in July, August, and September, and the mean maximum solar radiation was highest in April. Rain fell during all the months except October and December, the number of rainy days during the year amounting to 109. The maximum monthly total rainfall and the maximum fall in 24 hours both occurred in June.

Price of food. The price of food was higher in 1896 than the average of the preceding ten years. Common rice sold in the average at Rs. 4-14-6 against Rs. 3-9-11 per maund. Fuel and salt sold at about the same prices as the average of the previous decennium ; but the average price of meat, fruit, fish, vegetables, *dal*, *ghee*, and oil was higher than the average of the preceding ten years.

Vital statistics. The number of births (born alive) recorded during the year 1896 was higher than that recorded in any of the previous seven years, except 1892 and 1893. There were 12,608 births, giving an annual birth-rate of 18·4 per 1,000 of population. The figures for the past eight years are as follows :—

Year.	No. of Births.	Birth-rate.
1889	12,317	18·0
1890	11,918	17·4
1891	12,477	18·3
1892	12,688	18·6
1893	13,492	19·7
1894	11,438	16·8
1895	10,945	16·0
1896	12,608	18·4

As usual, the greatest fertility was exhibited by the Christians and other classes, and the birth-rate was greater among the Hindus than among the Mahomedans. According to locality, the birth-rate was greatest in the added area of Burtollah, in Hastings, and in the town area of Shampooker, and was least in Waterloo Street, Burrabazar, and Jorabagan. The male births fell below the female births in three districts, viz., added area Moocheepara, Baniapooker, and Khidderpur, and male and female births were equal in number in two districts, viz., Puddopooker and Park Street ; in all the remaining wards the male births exceeded the female births, the excess being greatest in the added area of Shampooker, in Bamunbusti, Burrabazar, and Colootolah wards.

The general mortality of the town during 1896 was less than that of the previous year, but exceeded the average of the preceding five years. There were 24,356 deaths from all causes, being a mortality of 35·7 per 1,000 of the population against 27,031, or a ratio of 39·6 in 1895, and against 22,254 or a ratio of 32·7, the mean of the five years 1891 to 1895. The following figures give the numbers of deaths and death-rates in Calcutta during the past eight years :—

Years.	No. of Deaths.	Death-rates.
1889	19,564	28·7
1890	20,368	29·8
1891	21,517	31·5
1892	20,180	29·6
1893	20,103	29·5
1894	22,441	32·9
1895	27,031	39·6
1896	24,356	35·7

The decline in the public health in comparison to the previous five years was greater in the town area than in the suburban area, and in the area bordering on the Circular Canal than in the rest of the suburbs. The death-rate in the town proper rose to 33·1 in 1896 against 29·4, the average of the previous five years, while the death-rate in the Suburbs rose to 41·2 in 1896 against 39·6, the mean of the previous five years ; and the ratio in the canal area was 42·6 against 37·8, and in the rest of the suburbs 34·7, excluding the hospital deaths that cannot be referred to any of the wards of the town, against 34·2. In comparison with the five years from 1891 to 1895, the unhealthiness of the town was practically universal throughout the town area, the Park Street ward alone forming an exception, and even in that ward the public health was virtually the same in 1896 as in the previous five years ; but in the Suburbs, the three wards Ballygunge, Bhowanipur, and Alipur, shewed a decided improvement in the general health in comparison with the average of the five previous years, though the Suburbs generally shewed a deterioration in health from the previous five years.

Statement of Deaths from different causes during 1896.

1. No. of Wards.	2. Names of Wards.	3. Population according to Census of 1891.	4. Cholera.	5. Small-pox.	6. Fever.	7. Dysentery and Diarrhœa.	8. Injury. Suicide. Male.	Suicide. Female. 	Total of Municipal Calcutta ..	6,81,560	3,449	69	9,564	2,967	42	41	276	3	362	7,945	24,356	5·0	·1	14·0	4·3	·5	11·6	35·7	32·9

On the other hand, in comparison with the previous year, there was in 1896 an improvement in the general health of all the wards except six, namely, Sukeas' Street, Burrabazar, Waterloo Street and Hastings in the Town Proper, added part of Moocheepara in the canal area and Watgunge ward in the Suburbs.

As usual the mortality among females was higher than among males, the ratio being 41·7 and 32·5 respectively. The fall in mortality during 1896 from the previous year was due to a fall in the mortality among both males and females.

In comparison with the previous year there was a fall in the death-rate at all ages during the year 1896, the fall being particularly great under the age of five years. The figures are as follows :—

Year.	Under 1 year.	1 to 5 years.	5 to 10 years.	10 to 20 years.	20 to 40 years.	40 to 59 years.	60 years and upwards.	All ages.
1895	476·0	80·4	25·8	18·6	25·9	29·3	78·4	39·6
1896	435·4	50·4	22·3	17·1	24·2	28·5	74·0	35·7

The mortality of infants under one year of age, though below that of the previous year, was still very high. There were 4,265 deaths, being a mortality of 435·4 per 1,000 of the infant population. The mortality was much greater in the urban than in the suburban area of Calcutta, being 494·7 against 347·2 per 1,000 of infant population. It was greater in males than in females, and it was as usual greatest among the Mahomedans and least among the Christians.

The death-rates according to nationality during 1896 were lower than during 1895. The figures for 1896 are 25·4 for Christians, 36·6 for Hindus, 34·9 for Mahomedans and 45·6 for other classes against 30·9, 40·2, 39·0 and 59·0 respectively in the previous year.

The factor which contributed to the fall in general mortality in 1896 in comparison with the previous year was a considerable fall in fevers, bowel complaints and small-pox, as under the remaining causes there was an increase in mortality. This is shewn by the following figures :—

Year.	Fevers.	Small-pox.	Bowel complaints.	Cholera.	Other causes.	Total.
1895	11,345	2,220	3,269	2,099	8,098	27,031
1896	9,564	69	2,967	5,449	8,307	24,356

The decrease in the mortality from fevers, small-pox and bowel-complaints and increase in that from cholera and other causes took place alike in the town and in the suburban area.

Fevers.

The deaths from fevers in Calcutta during 1896 were fewer in comparison with those during 1895, but were more than the average of the previous five years. The total number of deaths recorded in Urban and Suburban Calcutta was 9,564, which is a decrease of 1,781 deaths from the number registered in 1895, but exceeds the mean of the five years from 1891 to 1895 by 791 deaths. The figures for the Town and Suburban areas and for the whole of Calcutta were :—

Period.	Town Area.		Suburban Area.		Total Calcutta.	
	Number.	Ratio.	Number.	Ratio.	Number.	Ratio.
Year 1896...	6,075	13·0	3,489	16·2	9,564	14·0
Year 1895...	6,831	14·6	4,514	20·9	11,345	16·6
Average of 5 years 1891–95 ...	5,320	11·4	3,453	16·0	8,773	12·9

From these figures it will be seen that in 1896 there were in the Old Town 756 and in the Suburbs 1,025 fewer deaths than in 1895, but that compared to the average of the five years from 1891–95 there were in the Old Town 755 and in the Suburbs 36 more deaths in 1896. So that though in comparison with 1895 the year 1896 was healthy as regards fevers, still when compared with the previous quinquennium the year under report appears unfavourable in respect to this class of diseases.

The number of deaths from fevers in Urban Calcutta during 1896 was, with the exception of that of 1895, the highest on record ; and if the year 1896, which was specially unhealthy in respect of fevers not only in Calcutta, but throughout the province of Bengal, be left out of consideration, it appears that ever since the year 1889 there has taken place a gradual but steady increase in the fever ratio in the old town.

Small-pox.

The mortality from small-pox during 1896 was very much less than during the previous year. There were only 69 deaths in 1896 against 2,220 deaths in 1895, and against an average of 539 deaths during the five years 1891 to 1895. Of these, 40 deaths occurred in Urban Calcutta and 29 in Suburban Calcutta, while the Port was free from the disease.

It was reported last year that the epidemic of small-pox which prevailed in the beginning of the year 1895 continued unabated up to April of that year. In May it began to decline and died out altogether in September. From October to December, 1895, there was not a single case of the disease among the residents of Calcutta, though cases were imported into the town by steamers arriving in Port and by the disease occurring among the newly arrived coolie recruits. In January 1896, a case of death from small-pox was reported from Beebibagan, Ward No. 19, Entally. The patient was an old woman of 60 years and was resident of the place. She was inoculated in her

infancy ; she died, and the Vaccination Department received information after her death on the 25th January 1896. As this was the first case amongst the residents of Calcutta after a long time, special enquiry was made by the Deputy Superintendent of Vaccination to trace the source of contagion, but no definite information on the subject was obtained. Her relatives said that she did not go out of town nor came in contact with any case of small-pox before her illness. On the 27th January a case of small-pox came to notice at Bokulbagan, Bhowanipur Ward. The patient was a Hindu male adult and came from Midnapur 8 days before his illness, there being cases of small-pox in his village at the time he left. He was vaccinated in his infancy. He was removed to hospital and got well. As vaccination and re-vaccination were vigorously carried out in both the above localities, no fresh cases occurred in them.

Of the 69 persons who died from small-pox during 1896, 17 were reported as vaccinated, 12 were reported as inoculated, and 40 were reported as unprotected, while none of the persons had had natural small-pox.

Cholera.

The mortality from cholera, during the year 1896, was very large in excess of the previous seven years. The number of deaths was 3,449 against 1,976, the septennial mean, giving a death-rate of 5·0 against 3·0 per 1,000 of the population. Of these, 2,377 deaths took place in Urban Calcutta, exceeding the mean of the previous ten years by 1,123, and 1,072 deaths occurred in Suburban Calcutta, exceeding the average of the previous seven years by 220. The figures for the two areas are as follows :—

—	1886.	1887.	1888.	1889.	1890.	1891.	1892.	1893.	1894.	1895.	1896.
Old Town	1,741	1,198	1,734	1,079	963	1,553	1,257	596	1,118	1,302	2377
Suburbs	—	—	—	1,236	916	1,402	762	273	577	797	1,072
Total Calcutta ...	—	—	—	2,315	1,879	2,955	2,019	869	1,695	2,099	3,449

The mortality during 1896 was greatest in the added area of Shampooker Ward with a death-rate of 8·7, while it was lowest in Collinga Ward with a death-rate of 1·3. The average ratio of the town, namely, 5·0 per 1,000, was exceeded in eight of the Urban Wards, and in the added areas of all the extended wards. Next to the added area of Shampooker, the Wards Burtolla and Coomartooly suffered most from cholera during the year 1896.

The monthly mortality is shewn by the following figures :—

January	199	July	47
February	263	August	13
March	772	September	13
April	1,214	October	34
May	538	November	42
June...	197	December	117

These figures shew that the heaviest mortality, as in the previous year, was in the months of March, April and May. In fact, the cholera mortality during those three months amounted to nearly three-fourths of that of the whole year 1896. Towards the close of the first quarter of the year, it was observed that numbers of persons living in houses in the neighbourhood of certain public bathing-platforms and making use of them were being affected with cholera. This circumstance and the fact that the public bathing-platforms were supplied with unfiltered water drawn from the river Hooghly in the port of Calcutta made it desirable to have the water of the river and the public bathing-platforms examined bacteriologically. The results of such examination shewed that *comma bacilli* were in the river and bathing-platform waters, and that the highest percentage of instances in which *comma bacilli* were found to be present in the water was

practically synchronous with the greatest prevalence of cholera in the town, as illustrated by the following figures for the seven months from January to July:—

——	January.	February.	March.	April.	May.	June.	July.
Number of deaths from cholera ...	199	263	772	1,214	538	197	47
Water from Hooghly river—percentage of samples in which *commas* were found.	9·0	16·2	48·6	61·5	21·7	23·8	—
Water from bathing-platforms—percentage of samples in which *commas* were found.	—	—	53·0	57·4	4·1	—	—

The use of the public bathing-platforms, under the circumstances, was considered to be dangerous to the public health of the town; and it was, therefore, recommended that those platforms should be supplied with filtered water instead of unfiltered river water, and that to prevent the possibility of bathers contaminating the reservoirs at the platforms, such reservoirs should be in the form of closed cisterns provided with side-taps.

Dysentery and diarrhœa.

The mortality from dysentery and diarrhœa was lower in 1896 than in the previous year, but exceeded the average of the previous seven years. There were 2,967 deaths against 3,269 in 1895 and against 2,840, the mean of the seven years from 1889 to 1895. Of these, 1,451 deaths occurred in Urban Calcutta, exceeding all the corresponding figures of the preceding decade except 1894 and 1895, and 1,516 deaths took place in Suburban Calcutta, which is in excess of the corresponding figures of five of the previous seven years.

Other causes.

The mortality from all other causes in 1896 was higher than that of 1895, and also exceeded the mean of the previous seven years by 138. There were 8,307 deaths against 8,098 in 1895 and against 8,169, the mean of the preceding seven years, being a mortality of 12·1 against 11·9 and 12·0, respectively.

Vaccination.

Vaccination against small-pox was carried on vigorously during 1896; but owing to small-pox not being extensively prevalent in the town, as it had been during the previous year, the number of vaccinations performed fell much below the number of 1895. Total number vaccinated during the year 1896 amounted to 11,976 against 54,982 of the previous year. Of these, 9,450 were cases of primary vaccination and 2,526 of re-vaccination. The corresponding figures for the year 1895 were 15,184 and 39,798 respectively. This shews a decrease of 5,734 primary vaccinations and 37,272 re-vaccinations.

Of the 9,450 primary vaccinations, 8,585 or 90·8 per cent. were successful, 360 or 3·8 were unsuccessful, and in 459 or 4·8 per cent. the result could not be ascertained. In primary vaccinations the rate of success calculated on the ascertained cases was 95·4 per cent. Of the 2,526 re-vaccinations, 248 or 9·8 per cent. were successful, 1,026 or 40·5 per cent. were unsuccessful, 460 or 18·2 per cent were doubtful, and in 792 or 31·3 per cent. the result was not ascertained. The rate of success on ascertained cases in re-vaccinations was 14·3.

Of the total number vaccinated 6,557 were males and 5,419 females. According to nationality, 431 were Christians, 8,471 were Hindus, 2,969 were Mahomedans and 105 were other classes; and according to age 2,936 were under one year, 6,241 were of one year and under six years, and 2,799 were six years and upwards.

Vaccination is carried on in Calcutta under the provisions of the Compulsory Vaccination Act. The Registrars of Births issue notices to parents or guardians of children at the time of registrations to have the children vaccinated within one year from birth; and notice of the registration is at the same time sent to the Vaccination Department. When a child has been vaccinated and the result of the operation ascertained, a certificate shewing the result of vaccination is given to the child's parent and the duplicate of it is sent to the Ward Registrar, who thereupon makes an entry in his register to shew that the child has been vaccinated. The Registrars submit the Health Officer monthly statements of persons of whose children they do not receive certificates of successful vaccination within one year. By means of such statements prepared and submitted during 1896, it was found that 8,903 persons had failed to produce the statutory certificates of having had

their children vaccinated. These cases of default were enquired into by the Vaccination Department, with the result that 4,294 children were traced and vaccinated, 1,433 were found to have left town or changed abodes, 898 were not found at the addresses given, 671 had died, 1,147 were ill, 35 had natural small-pox, and the parents of 425 were left to be prosecuted. The actual numbers prosecuted during the year under this heading was 354, out of whom 11 were convicted.

Under the powers conferred on the vaccinators by the amended Act, house-to-house enquiry for unprotected children was daily made by the male and female vaccinators ; and where children over one year of age were found, notices were issued to their parents or guardians to have them vaccinated within 15 days. In this way 541 notices were issued during the year 1896. Many of the people served with notice got their children vaccinated within the prescribed time, but 291 had to be prosecuted. As in previous years, in localities like Jorabagan and Burrabazar, great difficulty was experienced in the cases of up-country people in obtaining the names of defaulting parents, and hence these could not be adequately dealt with by the law. In some cases where the names were obtained, the persons could not be identified ; and unless summonses were served personally, the Magistrates decline to make any order about vaccination. In consequence of these circumstances, vaccination is not making as much progress among these people as could be desired.

Besides the prosecutions noted above, prosecutions were also instituted against 147 persons for neglect to bring their vaccinated children for inspection. The total number of prosecutions under all heads by the Vaccination Department during 1896 amounted to 792 against 321 during the previous year. This increase was due to small-pox not being so prevalent in 1896 as it had been in 1895.

In Calcutta both the humanised and animal vaccines are in use. These were kept up by regular transmission, and used all the year round. The demand for animal *virus* is increasing yearly.

ABSTRACT OF REPORT OF THE MADRAS MUNICIPALITY FOR 1896-97.

(Lieutenant-Colonel G. M. J. Moore, C.I.E., President.)

The New Drainage Scheme.—In addition to Rs. 200,000 granted last year the Government has contributed Rs. 150,000 in the current year. The Commissioners at their meeting held on the 3rd March 1896 appointed a committee to consider G. O. No. 2140 M., dated 21st December 1895, passing orders on the Drainage and Water-Supply Schemes of the City of Madras. The committee had a trial sewer with house connections laid in Parish Venkatachella Iyer Street, which worked very satisfactorily. Five meetings were held. The committee's report on the New Drainage was submitted to the Commissioners and approved of by them at their Special Meeting, held on the 18th of November 1896, and submitted to Government for sanction. The Government in its order No. 209 M., dated 12th February 1897, has approved of the scheme as proposed by the Commissioners and has sanctioned the appropriation of the provincial grant of Rs. 350,000 towards the construction of the Drainage of Mylapore on the house connection system and to lay pipe sewers with house connections along Ice House and Sydenham's Roads.

Twelve new drains were sanctioned during the year, viz., 2 in 1st Division, 1 in 2nd Division, 2 in 3rd Division, 1 in 4th Division, 1 in 5th Division, 3 in 7th Division and 2 in 8th Division. 10 of them have been completed, one drain in 2nd Division and another in the 8th Division are in progress.

Water-Supply.—A scheme for the improvement of the water-supply was prepared by the Engineer on the lines laid down in his Hydraulic Survey of 1895 and submitted to the Commissioners. The cost of this improvement amounts to $6\frac{3}{4}$ lacs. The northern line referred to in paragraph 90 of last year's report was completed and opened for use on the 2nd May 1896.

The quantity of water supplied to the City during 1896–97 was 450,768,294 c. ft. against 366,709,545 c. ft. last year. The following are the analyses of water taken (1) from the pipes at two places within the town (1st and 8th Divisions), (2) from Delivery Channel at Kilpauk, and (3) from Red Hills Lake from which it will be noticed that there is an appreciable improvement in the Red Hills Water.

	Water from Red Hills Lake 10 ft. from mouth of Tower pipe and 2 ft. below surface.	Water from No. 4, Cottage Delivery Channel before it enters the charcoal strainers at Kilpauk.	Water from Lamp post fountain in Quible Island St. Thomé High Road.	Water from the last wall two tap fountain at Ghouse Moiden Saib Street, 1st Division.

Vaccination.

The total number of cases vaccinated during the year 1896-97 was 27,021, against 27,024 in 1895-96, showing a small decrease of 3 cases. Out of 27,021 cases vaccinated 16,028 were males and 10,993 females. 24,813 were successful, 1,044 unsuccessful, and 1,164 unknown. The unsuccessful and unknown cases were greater than in 1895-96 by 240 and 52 respectively, and this was due to the large number of revaccinations performed among prisoners of the jails, emigrant coolies, &c., who were released or embarked before the result of the operation could be inspected.

During the year 1896-97 1,779 cases were brought to the vaccine depôts to show the result of the operations, and in 21,510 cases the results were ascertained by the Divisional Vaccinators under bye-law 11 and certificates of success were granted to the parents and guardians after inspection at their own houses. These results were again verified by the Deputy Inspector and 4 Assistant Deputy Inspectors. The cases vaccinated in the Penitentiary, Civil Debtors' Jail, and Emigration Depôts (Natal and Mauritus) were inspected by the Deputy Inspector. Out of a total of 27,021 cases vaccinated more than 50 per cent. were inspected by these officers.

Excluding the unknown cases from the total vaccinated, the percentage of success in primary and revaccination was 95·96, against 96·89, showing a decrease of 0·93 per cent. due to the large number of revaccinations done during the year.

During the year vaccination was carried on in 9 depôts, in 7 of them tri-weekly, in one (Thousand Lights) bi-weekly, and in one (Egmore) weekly. 123 inoculated calves and 376 tubes of lymph were sent on application to vaccinate persons in their own houses. 147 calves were sent to the Penitentiary to vaccinate the prisoners and 45 calves to the Natal Emigration Depôt to vaccinate the coolies. Calves were inoculated in the Central Depôt, Chintadripet, and sent to the other depôts on the working days.

Out of 27,021 cases vaccinated 1,779 were Europeans, East Indians, and Native Christians, 2,509 Mahomedans, 22,731 Hindus, and 2 other castes. Of the total number vaccinated 19,193 were primary vaccination, against 18,877 in 1895-96, showing an increase of 316 cases. The percentage of success, in primary vaccination was 99·19, against 99·66 in 1895-96, showing a decrease of 0·47 per cent. There were 7,828 cases of revaccination with 87·11 per cent. of success, against 89·76 in 1895-96, showing a decrease of 2·65 per cent. The high percentage of success obtained in revaccination in Madras has repeatedly been commented on in Reviews of the Annual Report, and doubt thrown on the accuracy of the statistics. These results, however, though they compare very favourably with English ones, and especially with those of army revaccination, which are obtained from humanised lymph or from points, are not so good as those of some Continental towns where revaccination is done direct from the calf as is the practice in Madras. The following statement shows the results obtained both in primary and revaccination :—

Year.	Primary Vaccination.				Revaccination.			
	Successful.	Percentage.	Unsuccessful.	Unknown.	Successful.	Percentage.	Unsuccessful.	Unknown.
1895-96	18,598	99·66	62	217	6,510	89·76	742	895
1896-97	18,789	99·19	153	251	6,024	87·11	891	913

The number of infants vaccinated under one year of age during 1896-97 was 13,129 children, against 13,187 in 1895-96, showing a decrease of 58 cases, with a percentage of success of 99·36 against 99·74.

Vital statistics.

Births.—The births registered during the year 1896 numbered 18,684, exclusive of still-births, being 453 less than the previous year, but more than any other year in the decade. The ratio per 1,000 per annum calculated on the census population of 1891 was 41·2, and on an estimated population for 1896 38·6. The still-births numbered 504, being 2·7 still-births to 100 survivals. It is probable, judging from the general conditions prevailing in the town, that this figure is much too low, and that a number of still-births are not recorded. The male live-births numbered 9,555 and the female 9,129, the proportion being 104·6 to 100.

The Mahomedan birth-rate 46·8 per 1,000, was considerably above that of the Hindus 40·7, and of the Christians 39·1. As the Mahomedan death-rate is also above the average of the other castes, it is probable that the Mahomedan population is above the census enumeration.

Mortality.—The deaths registered during the year numbered 17,131, against 17,052 the previous year, the average for the decade being 17,744. The ratio per 1,000 calculated on the census population of 1891 was 37·8, but on the estimated population for 1896 35·4. The mortality was below the average of the previous ten years throughout the year, except in the months of May and June, when the mean temperature was the highest recorded since 1866. Though the mortality in Madras is generally comparatively low during the hot dry months, Chart I.* shows that there is an appreciable rise in May and that this rise was

* Not re-printed.

more marked than usual in 1896, when the temperature was abnormally high. This hot weather rise is most marked under fevers, but it is also apparent under dysentery and diarrhœa, both in the curve for 1896 and for the decade. From inquiries that have been made the somewhat paradoxical conclusion has been arrived at that the rise in fever mortality in the hottest part of the year is due to chill. This is attributed to people sleeping in the open, often on damp ground and without sufficient covering to protect them from the wind. This is quite sufficient to bring on an attack of fever in a malarial subject, and this conclusion is confirmed by the fact that many of these cases are complicated by pneumonia. It is not improbable that some deaths from insolation also occur amongst natives and are registered as "fever," but there is very little evidence on this head. The increased number of deaths from bowel complaints may also be in a large measure attributed to chill, but also in part to the large consumption of raw fruit, often fermented or unripe, by the poorer classes of the population at this time of the year. The bowel complaints at this time of year, when the ground is parched and dried up, are believed to be quite distinct from the epidemic diarrhœa and other bowel complaints specially connected with the soil, which usually cause a much greater rise in the mortality later in the year after the showers of the south-west monsoon have moistened the surface of the ground, producing favourable conditions for the organisms which flourish in a damp and polluted soil, and which decline after the heavy rains of the north-east monsoon have washed most of the filth into the sea and brought a fresh supply of water into the town storage tanks.

The Price of Food.—The price of food though high was fairly steady until near the end of the year, when a sudden rise occurred owing to the failure of the monsoon in many parts of the country and the consequent danger of famine. The normal given includes the years of scarcity since 1889 : if these were not included the divergence of the present prices from the normal would appear much greater. The prolonged dearness of the staple food grains cannot but exercise a potent influence on the mortality of the poorer classes, seeing that it is not counterbalanced by a proportionate rise in the wage of labour. The mortality has been high ever since the year 1889 when the scarcity commenced, though there has been no considerable epidemic during that period, except in 1891, when nearly 2,000 deaths were accounted for by cholera.

Meteorological Conditions.—From the Reports of the Government Astronomer it is apparent that the year was a decidedly abnormal one, the principal features being excessive temperature and deficient wind, accompanied by deficiency of rainfall during the first seven months and excess of rain in the last two months of the year. The highest shade temperature recorded was 112·4° on May 15th, the mean maximum for that month being 101·1°, and for June 99·9, both well above the average. North-easterly winds set in before the end of September, but very little rain fell till up to November 11th, after which nearly 50 inches fell in six weeks. The fall from October 15th to the end of the year was 52·9, against an average of 27·6 inches.

Mortality from different diseases.—A comparison of the relative mortality from different diseases in 1895 and 1896 shows that in the latter the small-pox mortality rose from 3 to 42, the highest number since 1891, that a marked rise occurred under measles, a slight one under dysentery and diarrhœa, the deaths from fever, cholera and "other causes" being lower. See also Appendix V., Table IV.

Statement of Mortality from the prevalent diseases in 1896 contrasted with that of 1895.

Years.	Small-pox.	Measles.	Fevers.	Dysentery and Diarrhœa.	Cholera.	Total.	Other Causes.	General Total.	Ratio per 1,000.
1895...	3	249	6,265	2,204	122	8,843	8,209	17,052	37·6
1896...	42	494	6,039	2,353	97	9,025	8,106	17,131	37·8
Average for 10 previous years.	30·1	405·2	5,269·0	2,959·7	475·6	9,139·6	8,604·7	17,744·3	39·2

Out of a total mortality of 17,131, 8,489 were males and 8,642 females, giving the proportion of 98·2 to 100. The number of deaths in the different castes was Europeans, East Indians and Native Christians 1,240, Hindus 13,631, Mahomedans 2,252 and others 8, giving the ratios per 1,000 31·2, 37·9, 42·5 and 13·4.

Small-pox.—During the year there was a considerable increase of small-pox, 194 cases with 42 deaths, giving a case mortality of 21·6 per cent. The incidence on the vaccinated and unvaccinated is shown in the following table :—

—	Attacks.	Deaths.	Fatality.
Unvaccinated	79	28	35·4
Said to be vaccinated but no marks ...	40	7	17·5
Vaccinated	72	7	9·7
Had previous attack of small-pox ...	3	—	—
Total ...	194	42	21·6

It is to be regretted that there are no statistics to show the number of vaccinated and unvaccinated persons in the town, for the unvaccinated population amongst whom 79 attacks occurred is a very small one compared with the vaccinated population as shown by the statistics of birth and infantile vaccination. The table however clearly shows the protective influence of a single vaccination so far as the mortality amongst those attacked is concerned, for the fatality amongst the unvaccinated was more than three and a half times as great as among the vaccinated. That 3 second attacks of small-pox occurred, none of which proved fatal, is in no way remarkable, for the protective influence of an attack in childhood diminishes in later life. There were apparently no cases among the revaccinated, and the supporters of vaccination do not claim that it affords a life-long protection. In this connection the following tabular statement is of interest, as it shows that amongst the unvaccinated small-pox is a disease of childhood, the victims either succumbing or becoming practically immune, whereas amongst the vaccinated but not revaccinated it is a disease of later life when the protective influence has diminished.

—	Total deaths.	Under 10 years.	10–20.	Over 20.
Unvaccinated... ...	28	24	2	2
Vaccinated	7	2	1	4

In this table the early incidence of fatal small-pox among the unvaccinated is well illustrated, but the number of fatal cases amongst the vaccinated is so small that any exceptional occurrence affects the proportions. If further evidence were available it would probably be found that the vaccinated cases that succumbed in childhood had only been operated on after contracting the disease, or could be explained in some other way, as statistics show that of vaccinated children only 0·5 per cent. contract small-pox under 10 years of age and of the 0·5 per cent. who contract the disease only 1 per cent. die. Out of the 75 unvaccinated who were attacked 45 were born in Madras and 9 were under the age of compulsory vaccination. The general inference is that had the town been less efficiently vaccinated the disease would have been much more widespread.

Cholera.—143 persons were attacked with cholera during the year. The deaths numbered 97 against 122 in the previous year, 0 in the 1st quarter, 3 in the 2nd, 56 in the 3rd and 38 in the 4th. The disease appears to have been imported in the 3rd quarter from Wandewash and Arcot into the 1st Division in which 45 out of the 56 fatal cases occurred.

Measles.—The epidemic wave of this disease which fell in 1894 when 190 deaths occurred appears to be on the rise again, the deaths in 1895 numbering 249 and in 1896 494. Under existing circumstances practically nothing can be done to check it. Isolation is at present out of the question and owing to the crowding of most houses in the town and the ignorance and indifference of the people in such matters it is almost impossible for any child to escape when once the disease gets into a house.

Fevers.—These diseases continue to exact a heavy toll on the population, accounting for 6,039 deaths in 1896 and a much larger number more or less incapacitated for work by sickness. The exact causes of the malarial fevers cannot be traced so long as the life history of their parasites outside the human body is unknown, but there is no doubt that

a polluted and water-logged soil favours these diseases, and when the sewerage of the town is effectively carried out the mortality may be expected to decrease. The 1st Division suffered the most severely with a death-rate of 16·7 from fevers alone, which is more than the death-rate of some towns from all causes. It is badly drained and contains a large number of poor paddy-boilers and weavers, who live crowded together in defiance of sanitary laws and easily succumb to any prevailing disease.

Bowel Complaints.—The deaths from dysentery and diarrhœa numbered 1,721 and 632 respectively against 1,536 and 668 in the previous year. The increased mortality from dysentery occurred in every Division except the 2nd, 3rd and 4th and was fairly spread over the year. Though there was an increase on the previous year the deaths from bowel complaints were well below the 10 years' average.

Plague Prevention.—Though Madras has fortunately remained free from Bubonic Plague yet precautionary measures against this disease have formed an important feature of the administration during the latter half of the year and the expenses incurred have made an appreciable increase in the expenditure.

In October a special staff consisting of 1 Sanitary Inspector, 2 Overseers and 2 Peons was appointed to inspect the passengers arriving from the North and ascertain their addresses for daily visitation by the Divisional Inspectors. To this staff a Hospital Assistant was subsequently added. After medical inspection was fully organised along the line at Arkonam and other stations and the passengers had their tickets marked with a special punch the work of the Perambore staff was limited to taking the addresses of such persons as had been passed at Arkonam, so as not unduly to delay the train. About the same time the Port Authorities were asked to inspect the crews and passengers of ships arriving from infected localities and take measures to prevent the importation of the disease into the town by that channel. The Post Master General was asked to disinfect the letters arriving from Bombay, which he declined to undertake. The erection of sheds at Perambore and Cassimode was decided on, vernacular notices about the plague and its prevention were circulated and a number of measures of a general character for improving the sanitation of the town were instituted.

Early in the year it was noticed that a large number of people were coming into Madras from Bombay and it was thought expedient to take more active measures for preventing the spread of the disease, if, as appeared by no means unlikely, it should be imported. The old Regimental Hospital and Lines in Old Jail Street on the borders of Black Town were lent by the Government of India and the Old Women and Children's Hospital, Egmore, now occupied in part as offices, was to be available after six hours' notice. A shed was erected in the compound of the latter for urgent use before the hospital could be handed over. Two bungalows were also rented at Perambore near the station for hospital purposes and a bullock cart was hired to attend daily at the station for ambulance work. Eight Equifex Spray Disinfectors of the wheelbarrow pattern and four Carter's covered ambulances were obtained from England. A limited staff, establishment and equipment, but sufficient to make a start with, were provided for the isolation hospitals, which were placed in charge of the District Surgeons, and the Surgeon General was asked to provide subordinate Medical Officers to take charge of them. The total hospital accommodation was then as given below, allowing about 100 square feet of ground area to each patient :—

Black Town, Native Infantry Hospital	..	...	26	patients.
,, The Armoury and other buildings	...	64	,,
Cassimode	2 sheds	60 ft. × 20 ft. each	...	20	,,
Krishnampet	,,	,,	...	...	20	,,
Perambore	,,	,,	...	...	20	,,
,,		bungalows	...	20	,,
			Total accommodation	170	patients.

The accommodation thus provided was capable of considerable expansion by the erections of sheds for which there was ample space available.

A few segregation sheds were erected as the nuclei of camps in the following places :—

Black Town	...	3 sheds with accommodation for	15	persons.
Vepery	...	3 ,, ,,	30	,,
Krishnampet	...	2 ,, ,,	18	,,
Perambore	...	3 ,, ,,	25	,,
Total ...	...	11 ,, ,,	88	,,

The Perambore sheds were for persons coming from infected localities who had no fixed addresses to go to.

On the representation of the Health Officer that the Municipal Act was absolutely inadequate for giving effect to the fundamental principles of preventive work, compulsory isolation, segregation and disinfection, an urgent application was made to Government for special powers to cope with the emergency, and communications on the subject took place between the Local and Supreme Governments. Shortly afterwards the Epidemic Diseases Act of 1897 was framed and passed, and Regulations under it for the City of Madras were drawn up and published in the *Fort St. George Gazette* of the 13th February 1897. These Regulations were translated into the vernaculars and widely circulated, in order that every citizen in the town should know what was required of him, and that people might be fully aware of the penalties they rendered themselves liable to for disobeying or contravening them. Thus with isolation hospitals, segregation sheds and regulations giving ample powers a much greater sense of security was felt and it was believed that any imported cases could be successfully isolated and dealt with. Under these Regulations the Municipal executive could enter any house and summarily abate a nuisance. Advantage was taken of this to eradicate a most objectionable form of nuisance consisting of an untrapped soil-pipe with no flushing tank connecting an upstair latrine with one on the ground floor, which had been introduced into a number of houses though never with the sanction of the Commissioners. Nearly 200 such tubes were removed by the Public Works Department at the instance of the Health Department.

About the time of the issue of the Plague Regulations the public of Madras was thrown into a state of perturbation by the announcement that the town had been made a pilgrim port and that a batch of pilgrims was about to be sent for embarkation. The Municipal Commissioners unanimously passed a Resolution protesting against this measure and requested that a public meeting of the citizens might be convened for the consideration of the matter. The Chamber of Commerce, Harbour Trust and other public bodies likewise protested. A public meeting was held in the Victoria Hall and a Resolution of emphatic protest was passed and telegraphed to the Secretary of State with the result that the obnoxious measure was eventually rescinded.

In order that the Health Officer might be free to devote his whole time to special work in the event of the plague appearing in the town, it was decided to appoint an Assistant Health Officer on Rs. 200 a month and Rs. 30 for horse allowance, and Mr. C. T. Mathew, L.R.C.P. & S., Edin., was appointed.

After the publication of the results of Mons. Haffkine's prophylactic inoculations in the Byculla Jail, it was suggested by the Health Officer that the measure should be introduced and that everybody who had been exposed to infection should be inoculated if he would consent to it. He also requested permission to go to Bombay to learn how to prepare the lymph and to study the immunisation of horses for curative serum and the general administration of one of the largest epidemics of modern times. The Commissioners, however, decided that he should not leave Madras, so syringes were indented for and the Bombay Plague Research Committee was asked to supply the prophylactic which was promised "when more urgent demands were satisfied," which apparently they had not been at the time of writing.

A number of false reports of plague were received but the correct diagnosis was in all cases easy, and up to the time of writing no true case in man or rat has been reported. No undue dependence, however, is placed on the fact that Madras is outside what is known as the "plague belt," being considerably below 20° N. Latitude, for it was found that the plague microbe remained healthy and produced strong colonies when cultivated on Agar under ordinary conditions in Madras.

ABSTRACT OF REPORT OF THE MUNICIPAL COMMISSIONER OF THE CITY OF BOMBAY FOR 1896-97.

(*Mr. P. C. H. Snow.*)

Special Drainage.—The unfinished works in progress in charge of the Special Drainage Engineer were the Colaba and Umarkhadi sewerage, Connaught Road and Sussex Road drainage and sewerage, Parel sewerage, Mazagon sewerage, Malabar Hill and Khambala Hill sewerage; while the following new works were commenced: House drainage connections (street portions), Colaba District; Fergusson Road and Chinchpokli sewerage (gravitation); a portion of, *i.e.*, 18″ pipe sewer, DeLisle Road; draining storm-water from the public roads around Mahaluxmi Dhobiwada; laying 9″ pipe drains for carriage of storm-water to the sea from the southern portion of Wodehouse Road. Several works were also sanctioned by the Corporation, but not commenced. **Public Works.**

Colaba Sewerage Works.—The works in pipe sewers were practically completed departmentally in February. The works connected with the air-compressing machinery, &c., were completed by 1st May, and all that remained to be done was the testing of the whole system of air-mains. The mains were finally tested, with satisfactory results at the end of the year, and the accounts of the works settled. The total cost, including erection, was Rs. 3,26,246-8-10. The other works connected with the Shone system in Colaba—engine-house, boiler-house, &c.—were practically completed by 1st October 1895. The expenditure on these was Rs. 80,908-14-2. The Umarkhadi sewerage was not completed until the end of May 1897. The expenditure on this work to the end of the year was Rs. 2,92,379-4-9. The Connaught Road and Sussex Road drainage and sewerage works were in the same position as last year. The Parel sewerage works were completed during the year, as were also the Mazagon sewerage works and the Malabar Hill and Khambala sewerage works (gravitation portion). The Shone system of sewerage worked uniformily well at Colaba, though it has not yet been possible to work up to full power, owing to the comparatively small number of houses connected and the small volume of sewage to be lifted.

Drainage.—The sewage pumping station at Love Grove worked satisfactorily, notwithstanding the excessive wear and tear to which the Worthington pumps are subjected. Although the rains of June and July were so excessive, the sewers were absolutely unaffected, all surplus discharging itself without difficulty through the Love Grove outfall.

House-connections with the drains.—The Corporation having decided, on the 18th June 1896, that the Municipality should bear the cost of constructing the street portions of the connections, and on the 3rd September sanctioned the advance of Rs. 100,000 for the purchase of materials, some advance was made, more especially after the outbreak of the plague. The scheme of converting the night-soil depôts at Bhangi Moholla and Haines Road into receiving depôts, with a view to lessening the qnantity of filth sent to Kamathipura, made but little progress on account of difficulties in obtaining labourers and of selecting a sight in Haines road.

Water Works—Tansa Lake.—The rainfall was 120·13 inches compared with 92·37 in 1895. The heaviest fall was on 29th July (8·30 inches) and there were excessive falls on the last ten days of that month. The lowest water-level was on the 15th June (395·14 T.H.D.), but after 30·34 inches had fallen the lake overflowed on the 5th July and the water continued to overflow until the 29th August. The quantity of surplus water passed over the waste weir was estimated at 27,700,000,000 gallons. The highest flood over the waste weir (1·80 feet) occurred on the 29th July. The approximate quantity drawn off into the duct from the lake was 8,569,000,000 gallons, of which 165,000,000 gallons were passed into Vehar Lake. The heavy falls of rain on 29th and 30th July flooded the duct line between Godavli and Balcomb, forming a continuous sheet of water for $3\frac{1}{4}$ miles. The embankment was seriously injured, and about 1,000 feet washed away from under the 48″ pipes destroying a portion and stopping the supply of water. The repairs took 18 days to complete, the staff working day and night in continuous heavy rain. In addition to this work, it was necessary during the year to make a temporary diversion of the 48″ main in order to make good a leak in the duct at the 44th mile, through which about 750,000 gallons daily were running to waste. This work was still in progress at the end of the year.

Vehar Lake and Dependent Works.—The rainfall was 109·81 inches, or 27 inches more than in 1895, and 25·97 inches more than the average of 1883-1890. The lake overflowed on the 25th July and continued to do so until the 28th August. The heaviest rainfall (9·78 inches) was on the 14th July. The lowest water level (252·70 T.H.D.) was on the 17th June. The storage on 31st October 1895 (11,010,000,000 gallons) was reduced by 31st May 1896 to 7,919,000,000. On 1st September following the storage had increased to 11,010,000,000. The daily loss during the dry season was 14·5 million gallons in addition to the water drawn from Tansa. Besides the water from Tansa, 1,800,000,000 gallons were received from the Tulsi Lake by overflow; the quantity of water passing over the waste weir was roughly estimated at 6,530,000,000 gallons.

Tulsi Lake.—The rainfall was 139·52 inches as compared with 100·40 in 1895, the heaviest fall (8·83 inches) being on the 14th July. The lake overflowed from the 23rd of July to the 27th August, to an estimated quantity of 1,800,000,000 gallons. On 31st October 1895 the storage was 2,136,000,000 gallons; on 31st May 1896 the quantity was reduced to 915,000,000. By 30th September 1896 it had increased to 2,156,000,000 The loss during the year amounted to 1,030,000,000 gallons, or 171,000,000 per month.

Pawai Lake.—No water was drawn from this lake, the pumping plant remaining in charge of the Assistant Engineer, Mechanical Branch. In February a further sum of Rs. 7,655-7-6 was paid into the Thana District Court on account of compensation for the land acquired for the duct line.

Bhandarwada Reservoir.—The old filters were worked till the beginning of December, when they were stopped for cleaning. Poor progress was made with the scheme for covering the storage basin and constructing filters over it. It was decided in June to substitute shingle for chips, and this led to the contractors removing the contracts, and the work will have to be completed, probably at increased cost, by other agencies. The expenditure incurred on the work during the year was Rs. 1,17,391.

Malabar Hill Reservoir.—The work of renewing the filtering materials was still in hand at the close of the year.

Distribution and Maintenance.—In connection with the plague, 1,180 house connections were cut off during the year and replaced by stand pipes in convenient situations. This, with the exodus of population reduced the consumption for some weeks, and the Tulsi supply was accordingly shut off from 25th January to 12th April 1897. There would have been still greater economy of water but for the large supply utilized for flushing purposes during the epidemic. The number of bursts during the year was 180 against 255 last year, and 313 in 1894-95. Apart from the work done on account of the plague, 230 services were cut off on account of demolition of buildings, non-payment of rates or the like, and 497 new connections granted. There were 2,047 meters in use on 31st March 1897, being an increase of 193. The consumption registered by meter aggregated a little under 1,259 million gallons.

Public Health.

The state of the public health during the year under review was very unsatisfactory. The mortality was 8,369 more than in the previous year. The total number of deaths from all causes amounted to 33,451, equal to a death-rate of 40·71 per 1,000 of population calculated on a population of 821,764 (Census of 1891). The average number of deaths for the previous five years amounted to 27,104, or a death-rate of 32·98 per 1,000 of population.

The number of deaths according to place of birth was as follows :—

Born in Bombay	13,637
Born elsewhere and unknown	19,814
Total	33,451

Cholera.—The number of deaths from cholera was 490, or 400 more than in the last year. The sections of greatest mortality were the Water Division, Girgaum, Dongri, Worli, Dhobi Talao and Parel. The highest death-rate by caste was amongst Lingayets, Hindu low-castes, Eurasians, Native Christians and Jews.

Small-Pox.—The deaths from small-pox were 701, or 431 more than in the last year. The rate of mortality was highest amongst Negro-Africans, Hindus of low-caste, Lingaets, Jains and Native Christians. The mortality was highest in 1st and 2nd Nagpada, Byculla, Tardeo, Worli, Girgaum, Dhobi Talao and Kumbharwada.

Measles.—There were 241 deaths from measles, or 303 less than the last year. Of these, 205 occurred in the first four years of life. Excluding the small community of Buddhists, the highest rate of mortality occurred amongst Lingayets, Jews, Hindu low-caste and Native Christians. The death-rate was highest in the districts of 1st and 2nd Nagpada, Tardeo, Kamatipura, Kharatalao and Dhobi Talao.

Fevers.—There were 8,776 deaths from fevers, or 2,372 more than in the previous year. The death-rate was highest in the districts of Kamathipura, Mandvi, Sewri, Kharatalao, Mazagon, Kumbharwada and Dongri. The greatest mortality was amongst Negro-Africans, Jains, Hindu low-caste, Lingayets, Mussalmans and Hindus of other castes.

Leprosy.—There were 54 deaths from leprosy, being 12 more than in the last year.

Bubonic Plague.—There were 1,936 deaths from bubonic plague during the year. A full report on the outbreak of this disease is under preparation for submission to Government, and will eventually be laid before the Corporation.

Births.—The number of births registered, exclusive of still-born, was 15,890, or 206 more than in the previous year. Of these, 8,267 were males and 7,623 females. Excluding Negro-Africans, the birth-rate was highest amongst Jews, Hindu low-caste, Parsees and Eurasians. The sections giving the highest birth-rate were Mahim, Sion, Kamathipura, Khetwadi, 2nd Nagpada, Tardeo, Fort Northern, Chukla and Parel.

ABSTRACT OF REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1896.

(*Surgeon-Lieutenant-Colonel T. S. Weir.*)

In the Report for 1895, although there had been a reduction in the mortality, I took a gloomy view of the future that has, I regret, come too true. I wrote as follows in the opening portion of the Report :—

" Although there has been a very great improvement in the Public Health this year, " the mortality being 2,249 less then in the last year, yet I cannot hope for further " reduction in the mortality until the local insanitary causes that I have so frequently " described, and which I will once more describe so that there may be no responsibility " on me, are removed. 25,081 deaths were registered, being 2,249 less than in 1894. " Of this reduction in mortality, 820 deaths were from diseases of the respiratory system, " 594 from diseases of the digestive system, 336 from cholera, 261 from small-pox, 243 " from measles and 54 from fevers."

The two previous years, 1893 and 1894, were remarkable ; the meteorological phenomena and the incidence of diseases not only amongst human beings but amongst animals being abnormal. The abnormal meteorological states of these two years were accompanied by the prevalence of zymotic diseases amongst human beings and animals.

In the report for 1893 I wrote as follows :—" I have, after the very unfavourable record " of 1892, to report in this year a very great improvement in the public health, the " mortality being 3,376 less than in that year, but only 197 less than the average. This " is so far satisfactory, but it will not and cannot continue unless that more effective " means for carrying away the water brought into the City are provided."

And again in 1896 I wrote :—" Although in 1895 there have been 2,249 fewer deaths " than in 1894, I must repeat again what I wrote in 1893, that this improvement in " public health, so far as represented by 2,249 deaths, will not and cannot continue unless " that more general and therefore more effective means are constructed for carrying away " the water brought into the city. It is true that the reduction in mortality over the " previous year indicates that the general health of the city was so much better, but it " does not indicate, when the figures are carefully examined, that the local causes of " disease have been proportionately removed. The reduction is chiefly due to a lower " mortality from diseases whose prevalence I have always contended was due, not to local " conditions, but to general seasonal influences, although the mortality from each type of " disease was influenced and intensified by local conditions. The reduction in mortality " due to fevers is not considerable, being 54 less than in the last year and 273 below the " average. The chief reduction has been caused through a diminished mortality from " cholera, small-pox and measles, or, in other words, the three chief zymotic causes and " the group of diseases which accompany or are synchronous with them."

I classified the local causes unfavourable to the public health in the following order :—

I. Insufficient drainage—
- " (*a.*) Sewage.
- " (*b.*) Subsoil water.
- " (*c.*) Absence of connections between building and sewers."

II. Overcrowding.

III. Disposal of all the dry refuse on the Flats, Tardeo.

IV. The imperfect provision in the Municipal Act in regard to—
- (*a.*) Rebuilding of houses on old foundations without a " space for ventilation and " drainage being left on one side."
- (*b.*) The exclusion of the evidence of Municipal Officers " in regard to nuisance."

V. The obstruction of the sea-current around the Island by the " embankments at " Bandora and Coorla."

The important works accomplished or in progress during the year are :—
- (*a.*) The completion of arrangements for the removal of the refuse outside the island.
- (*b.*) The completion of house-connections in Lalwadi.

(*c.*) The completion of the Shone system in Colaba and the commencement of house-connections to the system.

(*d.*) The advancement of the drainage work in Nagpada and Umarkhadi and other portions of the city.

Before examining the statistics of mortality I must refer to the admirable regularity with which the sanitary work proceeded. It was the only work in Bombay not interrupted by the panic created by the plague. The removal of the refuse from buildings and from streets proceeded with the regularity and with even more than the vigour of ordinary years. The establishment deserves well of the city. Even the clerks, although they received no reward, did not follow the general example of those employed in private firms who deserted their duties.

Exclusive of still-born, 33,451 deaths equal to a mortality of 40·7 were registered, being 8,370 more than in the previous year and 8,267 more than the average. Of this excess mortality, nearly one-half occurred in the month of December. It will hereafter be shown that the excess mortality was distributed over 10 out of the 32 sections of the city, that in 13 sections the mortality was under 35 per 1,000, and that in four sections on the west side, Fanaswadi, Chaupati, Walkeshwar and Mahalakshmi, the death-rate fluctuated between 28·29 and 17·63 per 1,000.

The mortality amongst all classes except Europeans was higher than in any previous year since 1877 ; the mortality of the four chief classes varying from 53 per 1,000 amongst Mussulman to 19 per 1,000 amongst Europeans.

From the table printed hereafter showing the mortality according to place of birth, it will be observed that the number of deaths amongst persons born outside Bombay is as many as 5,945 in excess of the number born in Bombay. The mortality by place of birth, therefore, clearly indicates that there must have been during the year a great migration of people into Bombay.

TABLE shewing the NUMBER of DEATHS, exclusive of STILL-BORN, according to PLACE or BIRTH.

Months.	Bombay.	Elsewhere.	Unknown.	Total.
January	881	1,273	17	2,171
February	970	1,257	26	2,253
March	1,096	1,415	23	2,534
April	1,100	1,449	16	2,565
May	1,073	1,339	15	2,427
June	956	1,047	26	2,029
July	1,157	1,127	15	2,299
August	1,134	1,514	21	2,669
September ...	1,050	1,542	24	2,616
October	1,077	1,785	6	2,868
November... ...	1,002	1,876	11	2,889
December	2,141	3,958	32	6,131
Total	13,637	19,582	232	33,451

When the increase in the total mortality is studied closely, and examined especially in reference to the place of birth, it will be seen that the statistics demonstrate one of two things—either that the increase in the mortality in August was not due to Bubonic Plague, or that, if it was due to Bubonic Plague, the disease affected, out of the population, only the classes born outside of Bombay. Any conclusions drawn from the total excess of mortality in August over the average mortality of the previous five years without a careful examination into the causes and incidence of the excess, and without due consideration being given to the causes of that excess, are likely to be either illusory or incorrect. Moreover, when the mortality by months according to place of birth is examined, the surprising fact appears that, while the total mortality in August had increased by 370 over the number of deaths in July, the mortality amongst the people born in Bombay had decreased by 23, the increase, amounting to 387, in the mortality being amongst persons born outside of Bombay. Still more surprising is the fact that in September the mortality amongst persons born in Bombay continued to fall and decreased by 84, while in October it increased by only 27 ; but in November it again decreased, the most surprising fact of

all, by 75, while all these months from August to November the mortality was steadily increasing amongst the people born outside the City. It would, therefore appear that, either the people born outside of Bombay had brought the disease to Bombay or were more susceptible to the pestilence than the people born in Bombay.

Months.	Deaths.	
	Born in Bombay.	Born outside of Bombay.
July	1,157	1,127
August	1,134	1,514
September	1,050	1,542
October	1,077	1,785
November	1,002	1,876

These facts demonstrate that mortuary statistics cannot be treated as mere items in an account. I shall give another proof of the care necessary in drawing conclusions from mortuary statistics, although such demonstrations are familiar to every student of the subject. At the worst time during this epidemic, the mortality in one section (the Fort, South) never rose above 26·32 per 1,000. For the whole year 1896, the mortality in this same section (the Fort, South) was only 5·31, while in the City the general mortality was 40·70. If, therefore, mortuary statistics are to be received as ordinary items in a bill the chances of life are seven times greater in the Fort, South, than in the rest of the City. This reduces absolute conclusions drawn from mortuary statistics without any reference to the conditions influencing the mortality to an absurdity. We are, therefore, forced to accept one of three conclusions in regard to the increase of the mortality in August if the enhancement in the number of deaths was due to Plague—(i.) either the Plague was prevalent in a number of places outside Bombay, 2, or that it chiefly affected persons born outside of Bombay ; (ii.) or that there was an immigration into Bombay of people (*a*) either affected with Bubonic Plague, or (*b*) peculiarly susceptible to it.

The mortality by class is generally high, and, except amongst Europeans and Eurasians, higher than in the last year. Excluding the small communities liable to great fluctuations, the highest mortality has occurred amongst Jains (62·83), and Hindu low-castes (63·27). The high mortality amongst Jains has been greatly influenced by the occurrence of Bubonic Plague in this community. The poorer classes of that community live under very unfavourable sanitary conditions, in overcrowded, ill-ventilated rooms and shops. Their manner of living is very poor, and a large number are scorbutic. The population is also a very fluctuating one.

The mortality amongst Hindu low-castes is equal to 63·27 per 1,000, against 47·22 in the preceding year. Whenever abnormal conditions are prevalent, disease is rife, and mortality is high amongst Hindu low-castes. Whenever the seasons are unfavourable and prices of food are high, the Hindu low-castes suffer most. They are very poor, and may often be seen searching amongst refuse for food. Their dwellings are in the most crowded buildings of the most crowded localities. Several families live in one room—a domesticity generally unknown amongst other classes. They usually sleep on the floor on a thin sheet, and in the rainy season the ground on which they sleep is damp and mouldy, and nearly as damp as the street outside. There can be no hope for the reduction of the high mortality in this class until the Municipality builds buildings for them and gives relief and charity, and even when the Municipality builds model chawls for them, there will be an immigration of the out-caste population from the Mofussil into the city. The overcrowding even under municipal management will not be easily combated. It is difficult to help the poor, and, of all poor, the out-caste poor are the most difficult to help. Relief helps them but little, as other friends from a distance are attracted to share it. Dwellings for them should be erected. In these dwellings overcrowding cannot be prevented, but the effects of overcrowding may be lessened. Let the dwellings be so ventilated that overcrowding in them will cause little harm—that the poisonous vapors from human beings will be dissipated by free ventilation.

In all the chief classes the female mortality is much in excess of the male. The heaviest excess is amongst Jains, Brahmins, Mussulmans and Native Christians.

The mortality from the chief death causes is shown in the following table :—

Table shewing Number of Deaths and Death-rate from different Causes during 1896.

Cause of Death.	No. of Deaths.	Death-rate per 1,000.
Small-pox	701	·85
Measles	241	·29
Fevers	8,776	10·68
Cholera	490	·60
Phthisis	4,809	5·85
Bubonic Plague	1,936	2·36
Diseases of the Nervous System	2,272	2·76
Do. do. Respiratory System	5,334	6·49
Diarrhœa	1,613	1·96
Dysentery	737	·90
Accidents	487	·60
Other and unknown causes	6,055	7·37
Total	33,451	40·71

The mortality from the chief causes of death shows an increased fatality as compared with 1895 from—

Small-pox	431	Respiratory System	769
Fevers	2,372	Nervous System	228
Cholera	400	Diarrhœa	425
Phthisis	1,199	Dysentery	112

The increase in the mortality from fevers, independently of the appearance of Bubonic Plague, is equal to 10·68 per 1,000.

The mortality by age periods follows nearly the same incidence as in former years, giving a higher female than male mortality; while in the last year the excess was only 12·90, in this year the excess is 14·31. The mortality amongst males under 2 years of age was higher than amongst females at the same period of life. Over 2 years of age the mortality of females commenced to rise until, at the nubile period, it was nearly double the male rate. Compared with the previous year, an excess mortality was registered at all age periods. The excess was greatest between 10 and 30 years of age amongst males and females.

Small-pox.—701 deaths were registered from small-pox, being 431 more than in the last year. There was a recrudescence of small-pox. Excluding the small population of Negro-Africans, the highest mortality occurred amongst Hindu low-castes—1·59 per 1,000. The next highest mortality occurred amongst Lingaets, Jains, and Native Christians. The mortality by age periods follows the same incidence as in former years, the highest occurring under 4 years of age. The mortality from small-pox fell heaviest on females. This is the normal incidence of the mortality in this city.

The mortality by sections is very interesting and instructive, because it is seen to be highest in the most insanitary and ill-drained districts, viz., the Nagpadas and Byculla. The six sections of the highest mortality were :—

1st Nagpada	1·97	Tardeo	1·36
2nd do.	1·70	Worli	1·29
Byculla	1·37	Girgaum...	1·25

Measles.—Although small-pox was epidemic, the mortality from measles is 303 less than in the last year. 241 deaths were registered, against 544 in the preceding year. I ascribe the decrease in the mortality from this disease to the loss of life at early ages from the epidemic of Bubonic Plague. Children died from Bubonic Plague who would have succumbed to measles. In former years the incidence of mortality from measles and small-pox has followed the same course. This year the decrease in the mortality from measles during a period when the fatality from small-pox is greater is abnormal. The mortality by class is distributed more evenly than in former years. Excluding Lingaets, amongst whom 1 death occurred, and Jews, amongst whom 3 deaths occurred, the highest mortality occurred amongst Hindu low-castes. Mussulmans have the next highest mortality—·34 per 1,000.

Cholera.—490 deaths were registered. The mortality from cholera was comparatively high in 1896, but in the previous year an exceptionally small number of deaths occurred; only 90 were registered in that year. In all 623 cases were reported, 490 of which terminated fatally. The fatality by sex is very unequal, 82 per cent. of the cases amongst males and 72 per cent. of the cases amongst females having died.

The harbour had the highest mortality; 30 deaths on a population of 22,142, giving a death-rate of 1·35 per 1,000. Most of the cases in the harbour occurred amongst the population living in boats off the foreshore. This floating population, exposed to the inclemency of the weather, and the emanations from a tidal foreshore, and careless about the storage of their water-supply, are liable to attacks of cholera or choleraic diarrhœa. The second highest mortality occurred in Girgaum, 32 deaths on a population of 26,999, giving a death-rate of 1·18 per 1,000. The first case occurred on the 18th of February. The third highest mortality occurred in Dongri, 35 deaths on a population of 30,317, giving a death-rate of 1·15 per 1,000. Worli had the fourth highest mortality, 25 deaths on a population of 25,493, giving a death-rate of ·98 per 1,000. Dhobi Talao had the fifth highest mortality, 39 deaths on a population of 39,945, giving a death-rate of ·97 per 1,000. The first case occurred on the 30th January.

The highest mortality from cholera, excluding the small classes of populations, occurred amongst Hindu low-castes (0·97) and Native Christians (0·84)—two classes living under most unfavourable sanitary conditions—especially Hindu low-castes. I have so frequently described the unfavourable conditions amidst which Hindu low-castes live, I need not refer to them again.

The disease became prevalent in July, and was most generally diffused in August. In July 108 cases occurred, 82 of which terminated fatally; and in August 179, 137 of which ended fatally. I ascribe the prevalence of the disease in July to the abnormal season and to the development of cholera germs in the rainy season.

Fevers.—From fevers 8,776 deaths were registered, being 2,372 more than in the last year, and 2,117 more than the average. Of the deaths from fevers, 7,293 were referred to remittent fever, being 2,143 more than in the last year, and 1,897 above the average. 1,167 deaths were ascribed to simple continued fever, being 244 more than in the last year and 251 more than the average. 36 deaths were referred to enteric fever, being 1 more than in the last year and 12 more than the average. The total mortality from fever shows that the highest fatality occurred in Kamathipura, Mandvi, Sewri, Khara Talao, Mazagon, and Kumbharwada. The mortality in Sewri and Mazagon was enhanced by the occurrence of cases of Bubonic Plague in these sections. The death-rate on the small population of Sewri was equal to 2·14 per 1,000.

The mortality by classes is most interesting. The mortality of Europeans is 11 less than in 1895. Europeans and Bhatias are the only communities in which the mortality from fevers was lower than in the last year. Curiously, amongst the small community of Lingaets the mortality was the same. The highest death-rate occurred amongst Jains. The mortality amongst Hindu low-castes was 3,939 higher than in the mass of the Hindu population, and 3,085 higher than amongst Mussulman. The mortality in the Parsee community rose to only 6·74 per 1,000, against 6·63 in the last year. The enhancement in the mortality amongst Parsees represents an increase of five in the number of deaths. It is remarkable that, although the mortality of Mussulman is high, yet the loss of life is less than in 1871, 1872, 1877, 1878, 1879 and 1880.

Phthisis.—The mortality from phthisis by sex shows the enormous loss of female life caused through seclusion in crowded, ill-ventilated dwellings. The female mortality from phthisis (8·1) is more than double the male (4·11), and this great excess of mortality falls chiefly on Mussulman and high class Hindu females. In the same classes there is also an excess mortality from the same disease amongst males, indicating that the chief cause is to be sought for in districts of insanitary dwellings.

Plague.

In July I was seriously alarmed by an outbreak of foot-and-mouth disease on this side of India and in the city; it suddenly subsided in August. This sudden outbreak aroused my apprehensions of some epidemic appearing, and measures were taken to prepare for such a visitation. Special attention was given to the state of the sewers throughout the city and to conservancy measures. The drainage of the district of Mandvi, in which the disease first appeared in an epidemic form, had given cause for great anxiety for some time. In the beginning of September my attention was drawn to four deaths that had occurred on Mandvi Bunder. None of the cases had been attended by medical men, and death was preceded by enlargement of the glands around the neck, and from the descriptions given to me the cases seemed almost like diphtheria.

The first public notification of this disease was by Dr. Viegas in the end of September, and Dr. Viegas deserves much credit for the diagnosis of the case. I had no doubt even

before as to the nature of the disease, and from the first the disease was treated as Bubonic Plague. But I hoped that, as before when cases of fever with glandular enlargement occurred, that the disease would not spread, and I believe we would have been as successful as at other times had the rats not been infected and had the year not been abnormal and food scarce and dear. It is true that the microbe in the laboratory is not affected by atmospheric changes, but looking over the historical invasions of the disease, it is difficult to believe that it is not influenced by conditions that favour or control the development of all forms of life, and that it has not its seasons of growth and decay. However, we have seen that the predisposition to the disease is influenced by the state of bodily and mental health and that those who were depressed either in mind or body were most often attacked and most frequently succumbed. In passing a judgment on the difficulties of recognition in the first cases, it has to be remembered that fevers with glandular enlargements are not unknown in Bombay, and that even now, with the knowledge possessed of the disease in its varying forms, and notwithstanding the suspicion with which cases of fever are regarded, the recognition of some cases of Bubonic Plague is most difficult, even in an hospital.

Public alarm was aroused after the expression of opinion by Dr. Viegas that the disease was true Bubonic Plague. I reported that the cases were engaging our most serious and constant attention.

An early case was seen by Dr. Ranina in August in Bhandup Street. The patient was unconscious when first seen; temperature 103. According to the history, given by friends of the patient, fever had suddenly come on without any premonitory symptoms. There was great pain in the left hip, which led to the discovery of two large glands below Poupart's ligament. Drs. E. F. and C. F. Underwood had before this treated some suspicious cases with œdema over the glands of the neck. I had been consulted and seen four of the cases, and of two of these cases I have been shown a photograph.

The recognition of the disease was due to its prevalence in one portion of the city, amongst a class who believed in medical men. Had the disease been of the more infectious type, the pneumonic without external glandular enlargements, had it been a rapid form of fever with slight cough, the type assumed by the plague during the epidemic period, there can be little doubt its recognition would have been very difficult. Dr. Viegas, therefore, displayed much acumen in the diagnosis of the first case.

Three deaths that occurred in Walkeshwar from fever and pneumonia in the week ending the 25th August 1896 attracted my attention. Two of the deaths were of mendicants and the third of a servant. In this week the mortality in Walkeshwar section rose to 40 per thousand, from 12 per thousand in the preceding week, and it again fell in the following period.

The fair in Nassick commenced on the 13th August, and large numbers of pilgrims from Upper India had passed through Walkeshwar on their way to Nassick. There are reasons for thinking, if not believing, that the event of the pilgrimage to Nassick had an important influence on the propagation of the pestilence in this city. It has to be recollected, in forming an opinion as to the period when Bubonic Plague commenced in Bombay, that synchronously with the increase in the total mortality in this city, there was an increase of the mortality in a number of places close to Bombay. For instance, in the Thana Collectorate, the mortality rose from 4,384 in July to 5,286 in August. In Surat City the mortality rose to 2,024 in July, and decreased to 1,886 in August. In Kurrachee the mortality, which had been 1,929 in January, decreased to 702 in August, and rose to 906 in September.

In the presence of these facts, it is difficult to ascribe the excess and the increase in the total mortality of this city in August to Bubonic Plague. The increase in the mortality of the city was synchronous with an increase in the mortality in a number of places around Bombay. If it is held that the increase in Bombay was due to concealed cases of Bubonic Plague, because no better explanation of the increase occurs, it may just as reasonably be held that the increase in the mortality in other places was due to the same cause.

The first cases reported to me seemed, from the description of the symptoms given by the friends, to be cases of diphtheria, and I may not pass over this opportunity of referring to other cases at a later period of a similar character and obscure type. Six cases, two of them of a very distressing type, were found in Mazagon on the 24th of February. They were a group of cases in one family that had been brought into Bombay from Thana. One of the family, a child, had died in the train, on the way to Bombay, from Bubonic Plague. Three of the cases had glandular enlargements around the neck. One of these, a female, had enormous œdema of the neck extending down below the clavicles on to the chest and into the axillæ.

There was great pressure on the trachea and gasping respiration. She died on the evening of the day I saw her. There was another case with enlargement over the parotid and submaxillary glands. This was a milder case and doing well. Undoubtedly, the cases were of plague, and yet bacteriologically the results of examinations obtained by two different observers were negative. Professor Bitter who saw the cases had no doubt as to the type of the disease and that it was Bubonic Plague. They were not dissimilar to the first cases in Mandvi described to me.

The time has not yet arrived to announce the date when the first case occurred in Bombay. We must wait till the experiences of medical men throughout India have been obtained. It is not improbable that when the disease has been more generally recognized and its different types distinguished—for even now some cases are most difficult of recognition during life—it will be found that cases of a disease not dissimilar in symptoms have occurred in periods not very remote, not only in Bombay, but in other parts of India. I have no doubt that the cases observed by Dr. Simpson in Calcutta were of Bubonic Plague.

In the Himalayan ranges and lower hills on the Indian frontier, the disease is endemic, and we have to remember that Bombay is in free communication with countries beyond India where the disease is endemic.

The following case treated in the Parel Hospital is of great interest, showing as it does the varying forms of the disease and how difficult these forms may at times be of recognition. Dr. Thomson writes :—" The German Scientific Plague Commission experts " found plague bacilli on three different days in the blood cultures, and the day before " death and at the *post-mortem* not a single plague bacillus could be demonstrated in the " blood of any of the organs. Their conviction was that the patient died from the severe " complication, and had his vitality been greater and no complication supervened, he would " certainly not have died of plague, all the bacilli being destroyed."

A very curious case was sent by me from Dongri to Grant Road Hospital. Some medical men present had doubts about the case. The case was of a boy suffering from mycetoma of the foot. He had no indications of Bubonic Plague, except a peculiar look about the face and a peculiar tongue covered with a white fur. The case was kept under observation. The Russian Scientific Mission made a culture from the foot and obtained plague bacilli. This case afterwards developed an abscess in the liver.

The desire of the people, when ill, to go somewhere, and especially to their country home, even when their homes are far away, was very remarkable. The same disposition I noticed in Europeans, when ill. In the course of the disease it is very remarkable the distance and number of the places to which numbers of wealthy and even poor people fled.

In the beginning we telegraphed to Lanowlee and other places giving information of people who had escaped from Bombay, and where they were supposed to be going. The first imported case noticed in Lanowlee was reported on the 14th of October. The first indigenous case in Lanowlee occurred on the 17th of April ; but it occurred a little outside the bazaar, and there was, as far as I could ascertain, no history and no suspicion of any recent case of importation.

The period of incubation in some cases appeared to be under two days.

Two very interesting cases were imported by sea. One case, a steward, who came direct in a steamer from Suez, landed, suffering from slight fever ; but afterwards the characteristic symptoms of Bubonic Plague appeared with enlargement of the glands on the right side of the neck. Temperature 105 ; respirations 55 at time of admission. The steamer had touched at no places between Suez and Bombay.

Two other cases I may refer to, both of which came from Assam to Calcutta and from Calcutta to Bombay by sea. The day after arriving in Bombay, they suffered from slight fever, and made up their minds to leave Bombay and go to Kurrachee. With this intention they took passages for Kurrachee and went on board the steamer. There they were examined, detained and sent to the Segregation Hospital in Reay Road. Both cases were afterwards removed to hospital.

In removing patients to hospital I saw many appalling instances of the rapidity of the disease and the suddenness of death. On one occasion I saw an opulent Hindoo in a crowded house, and I was asked whether he should be removed or not. I directed that he should be removed, but we did not tell the patient nor his friends. We thought we had better not till the ambulance came. I left for office, and before half an hour had passed and before the ambulance had come, I was told that he was dead. One felt thankful and had a feeling of relief that the sufferer had not been told that he would be removed to hospital and his last moments disturbed by fright.

The desire to wander—the delirium of the disease—is very strange and pathetic. A patient, with a temperature of over 100°, suddenly becomes influenced by this desire to wander. He leaves his house, and if he is wealthy, he drives to a railway station and tries to proceed to some place, and he cannot tell you why. I noticed this desire to wander in all classes, and it often precedes high fever and delirium.

As the epidemic proceeded people became alarmed in regard to the danger indicated by dead rats, and they commenced to write to us in the following strain, as this letter will show :—" As some dead rats are found in the house I am living in, and as I am afraid " that it is infected with the plague, I want to vacate it temporarily and live in some " sheds ;" and the letter finishes with a request to occupy some municipal land. In August there was a great increase in the mortality amongst cattle and sheep and goats. It will be observed from the table hereafter printed that there had been from July an increase in the number of dead animals removed. The small increase in the number of dead cats removed in July and August shown in the table will be observed. It will be observed that the mortality amongst horses decreased in these months.

Statement showing the Number of Dead Animals removed from May to September 1896.

Months.	Bullocks.	Buffaloes.	Cows.	Horses.	Calves.	Goats and Sheep.	Dogs.	Cats.	Other Animals.	Total.
May	34	28	17	59	410	66	325	36	9	984
June	42	30	15	51	456	67	282	34	13	990
July	38	31	11	29	712	88	184	41	19	1,153
August	47	30	22	23	870	117	224	44	18	1,395
September	48	33	16	31	733	104	206	36	9	1,216
	209	152	81	193	3,181	442	1,221	191	68	5,738

The people did not, and could not, believe that the disease was as dangerous as we pronounced it to be. They had been demoralized by the successes we had in dealing with infectious diseases. They expected that the new disease would be stopped as readily as cholera had in all former years been eradicated by our measures. The people here had no conception of the sacrifices willingly made in European cities for the prevention and suppression of infectious diseases.

Such a pass had we come to, that picking up a few sick pigeons caused excitement, and, nearly led to a riot, and peaceful Banniahs, for 10 sick pigeons, threatened to raze the city. Even the position of a dustbin was considered of public importance. All our attempts to kill or catch rats were opposed or threatened. It is difficult to persuade a people, with more regard for the lives of animals than for the safety of their own kindred, that it was right to kill or to capture animals either to stay the pestilence or to obtain a knowledge of the disease. I had hopes in September that a microbe, which Professor Hankin had a supply of, would when cultivated develop and destroy rats, but on being tried it was inert. We offered rewards for all dead rats found, and very general measures were taken to destroy rats and burn the dead ones. But soon the rats became scarce, or were not to be seen outside. While the rats were sick in Mandvi, the mice were unaffected, and in our office in that locality the mice, when rats could not be found in the district, were numerous and lively. So bitter was the opposition to the capture of rats that monstrous stories were invented of our officers throwing live rats on the fires, as if to give pleasure to men tired and weary, and knowing the danger of handling rats, doing what they need not do even if a sense of humanity did not forbid them. And so events proceeded, we were opposed on all sides, whether in the treatment of buildings, in the treatment of human beings, or in the treatment of animals. People whom we found sitting up and whom we begged to lie down, even before we left their doors, were again sitting up, and more than once before we left the building, we heard that they were dead ; as Dr. R. often said to me : " It is useless to give advice to the people." We had to deal with some people more careful of the lives of animals than of their own. We had to carry out measures opposed to the interests, the customs, and the dearest feelings of

some classes of the people :—1. To clean out houses when the people themselves would not either clean the houses or employ others to do it. 2. To remove the sick. 3. To burn or expose to the sun all articles likely to have been infected.

In the large buildings in Mandvi the tenants would not employ people to clean down the passages and spaces outside the rooms, as they said it was the duty of the landlords. They maintained that the landlords should do it, and we could not find the landlords. The Jains and others are a people very tenacious of their rights. People in these and other crowded buildings complained of everything outside and of nothing inside their dwellings ; to them a few leaves in a street or gully were a serious object of complaint, but the nuisances outside their own rooms and inside their houses they preferred to bear with rather than save the landlords the trouble of doing what they thought the landlords ought to do. It is a most serious defect in the law that there is no provision to compel landlords to employ an establishment to keep their houses clean.

On many occasions the ambulance vans were damaged even after the Plague Committee had been formed. One of my first duties in March was to go down to Falkland Road, as it had been telephoned to us that a large crowd had collected and stoned the ambulance van. On the way I sent Assistant Surgeon Pettigrew to bring up a detachment of soldiers from the Northbrook Garden. I found a very large crowd in the street, every lane being filled, and the soldiers had to drive the crowd back. Whether at the railway stations or in the city, nearly every hand was against the Municipal Officers, simply because people did not, and would not, understand that the disease was contagious. To show what strange customs prevail, I need only refer to the defence put forward in the Police Court, in a case where cows were kept on the ground-floor of a dwelling. The plea urged was that the cows were kept for religious purposes, the ladies of the household having to worship them in the morning. I believe the plea was true.

On the 29th of September a Committee was appointed by Government. The Committee had their first meeting on the 31st of September, and resolved that the Municipal Commissioner be requested to obtain sanction from Government to carry out, as far as practicable, the sanitary measures recommended by the Surgeon-General. The second meeting was held on the 9th of October, at which it was resolved that all cases recognized as Bubonic Fever should be carefully isolated or segregated in the best manner possible. Some discussion took place, and Dr. Viegas, after voting for the motion, said, that he had done so on the understanding that those cases which could be isolated or segregated in their own houses should not be removed.

On the 29th of September the Surgeon-General wrote to Government as follows :—

> " Firstly, then, I should suggest an immediate increase of the sanitary staff of the Municipality, " both in Medical Officers who may be chosen from local practitioners willing to serve, " and subordinates, with the special object of paying sanitary attention to quarters of the " city not yet known to be infected. I may here mention that two cases are said to have " occurred in the Fort last evening."

From the very beginning, I may mention, the measures suggested by the Surgeon-General had, as far as practicable, been carried out. The system of treating buildings in which cases occurred was the same all through the epidemic. There is no other system which could have been adopted.

One of the first orders I issued was, that every suspicious case was to be treated, for all practical purposes, as one of Bubonic Plague.

On the 6th of October, the Commissioner issued the following Notification :—

> " WHEREAS a dangerous disease, namely, Bubonic Fever, has broken out in certain parts of the " City of Bombay, and the Municipal Commissioner is of opinion that the ordinary " provisions of the City of Bombay Municipal Act, 1888, or of any other laws in force in " Bombay are insufficient for the purpose of effectually preventing the spread of such " disease, Public Notice is hereby given that, with the sanction of the Government, and " pursuant to the provisions of Section 434 of the said Act, the Commissioner hereby " prescribes the following temporary regulations to be observed by the public and all " persons concerned. And further that the Commissioner will, if necessary, take such " special measures as are hereby indicated for carrying into effect the objects of the said " regulations :—1. In extension of the provisions of Sections 422, 425 and 427 of the " said Act, it is hereby prescribed that every person having the control or charge of any " building, or part of a building shall, on demand by the Commissioner or any officer to " whom the powers, duties or functions of the Commissioner under those sections may " have been or may be delegated, immediately cause such building or part of a building " to be opened, and shall permit the Commissioner or any such officer as aforesaid to " cleanse and disinfect the same, to cause the removal for disinfection or destruction of " any grain, bedding, or clothing, or of any other goods or articles found therein.
>
> " For the purpose of carrying into effect the objects aforesaid, the Commissioner, or any such " officer as aforesaid, will, whenever he shall deem it necessary so to do, break open and " forcibly enter any such building or part of a building, and, without previous notice to " the owner or occupier thereof, will cleanse and disinfect the same, and direct or cause

" the forcible removal and disinfection or destruction of any grain, bedding, clothing, " goods, or articles as aforesaid. 2. In extension of the provisions of Section 424 of the " said Act, it is hereby prescribed that any person suffering from Bubonic Fever, " wheresoever found and whether provided with proper lodging or accommodation or not, " or whether lodged in a building occupied by more than one family or not, shall, on a " certificate signed by the Executive Health Officer or by any duly qualified medical " practitioner that such person is suffering from the said disease, be liable to be removed " to any hospital or place at which patients suffering from the said disease are received " for medical treatment. For the purpose of carrying into effect the objects of this " regulation, the Commissioner or any officer to whom the powers, duties, or functions of " the Commissioner under Section 424 have been or may be delegated, or any Police " Officer empowered by the Commissioner in this behalf, will, whenever he shall deem " it necessary so to do, cause any person in respect of whom such certificate as aforesaid " has been made to be removed to any such hospital or place as aforesaid. 3. Every " house in which any case of the aforesaid disease exists or has existed shall, for so long " as the Commissioner shall deem necessary, be isolated in accordance with such orders " as the Commissioner may in each case prescribe and every occupant of such house and " other person who may be therein, or who may resort or desire to obtain access thereto, " shall obey any order which he may receive from the Commissioner or any Municipal or " Police Officer empowered by the Commissioner in that behalf, prohibiting ingress to or " egress from such house. For the purpose of carrying into effect the objects of this " regulation, the Commissioner or any such Municipal or Police Officer as aforesaid will, " if necessary, forcibly prevent persons from entering or leaving such house."

The notification of the Municipal Commissioner of the 6th of October 1896 in regard to the regulations to be observed in the treatment of buildings where cases occurred, and of persons suffering from the disease, was received with loud denunciations, and answered by petitions protesting against its terms, and many classes of the population announced that they would leave the city, and undoubtedly they intended to do so. It was stated that the hospitals were places of torture and places intended to provide material for experiments. The Officers of the Health Department were charged with a brutal pleasure in dragging the sick from their homes and in killing them, and it was stated that our Sovereign Lady the Queen had demanded 500 livers of the people of Bombay to appease the wrath aroused at the insult offered to her statue. Men have said to me, " You think we are like mad dogs, and you want to kill us, as " if we were."

There were men, and aged men, from whom sage counsel and words of wisdom might have been expected, but who kept calling out, " Lost, lost ! " and crying to us, " Burn, burn." As people in a panic flying from danger unknown, so some in mad panic fled, they knew not whither. A fear seemed to have taken possession of the minds of some when all fear ought to have disappeared. Many fled from their own fears, and in flying frightened others. Some who might have been expected to be calm, if they did not remain silent, kept calling to others to fly and save themselves. They wantonly called on the Health Officer to burn down districts as if I had not chemicals to do, with not less certainty, what fire does.

A petition from a number of influential citizens was sent to the Commissioner on the 14th of October. It was stated that, hospital life being unknown amongst the people, the patient himself was most averse to being removed and deprived of the care and comforts he could count on in his family, and his removal was looked on, both by himself and his attendants, as certain death. In this petition it is stated that, if the regulations continued to be enforced, a much larger number of inhabitants would fly from Bombay. The petitioners demanded that the regulations should be carried out by all Municipal subordinates with care, judgment, and tact ; that friends and relatives did not like to part with their sick nor see them taken to hospital " recklessly " ; that " house measures " should not be entrusted to young and raw European and Eurasian lads ; otherwise there would be more discontent and panic, and so on.

It should be understood that the sick who were removed to hospital were not separated from their friends, as alleged. In the Arthur Road Hospital one or two friends were always allowed to attend upon the patients, and visitors were admitted into the hospital at all hours. In one case the Medical Officer wrote that a Hindu female was admitted with ornaments of the value of a couple of hundred rupees ; that the next day her relatives came to see her and took charge of the ornaments, and then went away, but never afterwards returned. The woman died, and her body had to be removed by the Municipal Authorities.

On the 15th of October, a Committee was appointed to enquire into the nature and history of the disease.

On the 20th of October, 500 mill-hands assembled on the road outside the Arthur Road Hospital and threatened to wreck the building and carry off the patients. On the

29th, some 900 or 1,000 mill-hands collected and rushed into the compound of the hospital and threw stones at the building, chasing the staff into the offices and inside the hospital. Even some of the patients were struck by the missiles and all were greatly terrified. The news of the disturbance was at once telephoned to the Police who promptly appeared on the scene. In this disturbance one of the ambulance vans was smashed, and the roof of the hospital damaged.

The mill-hands were a source of much anxiety. Yet they had been very considerately dealt with. Whenever a case had occurred in mill buildings occupied by mill-hands, or in other buildings, so long as it was fairly isolated, it was left alone. We had also agreed that if the mill-hands gave information of cases and isolated them, they would not be removed to hospital.

On the 30th October, the Municipal Commissioner issued the following notification, and I think it will be generally admitted that the terms of the notification were most reasonable and considerate :—

"WHEREAS the Municipal Commissioner is informed that great alarm has been caused to the "public by the Notification recently issued under Section 434 of the Municipal Act, and "whereas the objects of that Notification have been misunderstood, inasmuch as the powers "under it were obtained principally to meet the case of a large increase of Bubonic "Plague. The public are now hereby informed that no cases where proper segregation "and treatment can be carried out on the premises will be removed to the Arthur Road "Hospital, and in such cases as require removal no action will be taken except upon the "certificate of a qualified medical practitioner employed by the Health Department. "The Executive Health Officer has been instructed accordingly and the Commissioner "of Police informed."

On the 11th of December, a Committee, composed of members of different communities, was formed. At a meeting held on the 22nd of December, Mr. Hankin put his views before the Committee, and advocated the removal of the healthy from infected dwellings. The Committee approved of this recommendation, and appointed a Sub-Committee to ask the Municipal Commissioner to form camps where the healthy could reside. Previous to this the Commissioner had constant conferences with representatives of different communities. The Committee issued the following notice :—

"HOW TO AVOID THE PLAGUE.

"At a meeting of several influential citizens held on the 11th of December 1896, the gentlemen "whose names are given below, representing the different communities of this city, "were appointed to form a Committee to consider, amongst other things, the steps best "calculated to prevent the spread of the plague and to recommend to the people at "large the precautionary measures to be adopted to avoid the disease. The Committee "have been able, with the assistance of the best expert opinion, to prepare the following "rules which embody recommendations which should be carefully observed, and, in "order that these rules may be widely known to the public, the Committee have decided "to publish and circulate them in different languages in the form of handbills over their "signatures. The Committee hope that it will be clearly understood that the instructions "and recommendations contained in the following rules emanate from the Committee. "The names of the members of the Committee will, it is to be hoped, be a sufficient "guarantee to the different communities of this city that the recommendations made are "in the best interests of the people themselves and of the health of the city. In view "of the present dangerous state of public health, the necessity of keeping houses in the "town, and especially those in crowded parts, clean and free from bad smells, and of "following the instructions contained in the rules, cannot be too greatly impressed upon "the people. Light and air ought to be allowed to enter houses freely, and wherever "the means of ventilation are not sufficient it is extremely desirable that steps should "be taken to provide better ventilation, so that sunlight and fresh air may enter the "rooms. The Committee earnestly hope that the advice given by them, coming as it "does from the representative men of the different communities, will be cheerfully "accepted and acted upon.

In the rules the Committee gave excellent advice. They urged the people to inform the Municipality of all cases, and to leave infected houses. The danger of wet or damp places inside dwellings was pointed out. They advised the people to be careful of abrasions or sores.

They dwelt on the necessity of burning all articles that had come in contact with the sick.

Dr. BALCHANDRA KRISHNA BHATAVADEKAR.
Mr. K. N. KABRAJI.
Dr. ISMAEL JAN MAHOMED.
Professor O. V. MULLER.
Dr. A. D. MODY.
Dr. N. N. KATRAK.
} *Honorary Secretaries.*"

The Committee pledged themselves to use their influence to reconcile the people to the use of the segregation camps, but it was not possible to persuade the people and especially the poor at this time to enter either camps or hospitals.

The Commissioner put up excellent camps underneath bright coloured awnings, capable of accommodating some 1,500 people, one was erected in the Northbrook Gardens, and the other near Connaught Road, but people would not enter them although they were most attractive.

Many ingenious calculations have been made as to the decrease in the population during the epidemic, but conclusions based on an uncertain foundation, however much they may interest an enquirer in leisure moments, can scarcely deceive a student of statistics. The calculations made of the decrease in the population are all based on the population of 1891, and not on the numbers of the people at the time of the appearance of the epidemic. Speculation based on inferences drawn from calculations of the decrease in the population must be illusory if not vain. The fundamental fact—the increase of population between 1891–97—is not known. Conjectures as to the decrease in the population must be regarded with the interest which attaches to all speculation on a subject of so much importance and of so much interest to many of us. All that is known is that a certain number of people departed from the City by certain ways, by railways and by steamers, and that a certain number entered the City by the same ways. This information, although enough to give a vague or uncertain knowledge of the fluctuations of population, is not sufficient to afford an estimate of the numbers to which the population of the city was reduced. And, moreover, it is too often forgotten in these speculations that the rate of mortality greatly varies in different classes. While the class amongst whom the mortality is lowest, and whom we wished to remain, left the City in numbers ; the class—the poor, the out-caste, and the destitute from famine-stricken districts—whom we did not wish to remain, not only did not fly the city, but increased in numbers. The poor were always with us and increasing in numbers and in destitution.

I may quote the opinion of Mr. Baldwin Latham on the reduction of population between November and January, as he is an undoubted authority on mortuary statistics. He writes that the population of Bombay had been "reduced from 806,144 in 1891 to 723,336 " in the period of September and January last."

I believe that in this report for the first time statistics have been compiled and published, exhibiting the spread and marking the fatal path of the disease in buildings, through different classes of people and at different age periods.

Up to the end of the year, 2,544 cases of Bubonic Plague were reported. 1,936 of the cases ended fatally, giving a mortality of 76·10 per cent. The progress of the disease by months, as seen in the number of cases reported, indicates that not nearly so many cases escaped detection in the first months as was generally believed. In October the number of cases increased to 406, while in November, when the fear of removal to hospital had decreased, the number of cases fell to 339, but the fatality amongst those attacked rose, and in December, after the development of the epidemic, the percentage of deaths to cases it will be noted decreased. This shows that not many cases escaped detection.

The incidence of the mortality does not denote any great concealment of cases. It rather indicates the vigilance that must have been observed in examining buildings and in obtaining information.

TABLE SHOWING THE NUMBER OF ATTACKS AND DEATHS FROM BUBONIC PLAGUE IN 1896.

Months.	No. of Attacks.	No. of Deaths.	Percentage.
September	135	79	58·51
October	406	313	77·09
November	339	273	80·53
December	1,664	1,271	76·38
Total	2,544	1,936	76·10

In the crowded buildings in Mandvi in which the disease first appeared, we had over 100 people in many buildings and as many as 600 people in one building, one family living their life in one room, opening on to a common passage in which the grain was ground, and at one end of which was the water-pipe under which the clothes were washed, splashing the walls and floors around. We take for explanation one building in Clive Road. There are 116 rooms, and say there are 4 persons to each room ; it gives nearly 500 people to the house, and underneath this mass of people, densely pressed in one building, with the foulness that must come from human beings, are 3 godowns and

shops and yet this is not by any means the most crowded and densely populated dwelling in the city. No one can look at the size of the buildings and the number of rooms in each building in this locality as shown in the statement without having a feeling of astonishment that the mortality has been so low. They are most thrifty people, the Jains and other classes who come here for business from Gujerat or Kathiawar and live in these buildings ; they suffer as much from thrift as other classes from want of thrift ; they seldom eat fruit, and they use very little vegetables, unlike most Hindus. They are so thrifty that they collect rags and rubbish in the passages of the dwellings, and so careful of animal life that they fear to sweep near the rags they have with much pains bound in bundles. I have never seen any people so indifferent to the sight of the dying and the dead. This is what the Committee appointed by Government saw one evening during the inspection of a building. In one room of a large building with double rooms on each floor, was a patient ill from bubonic plague. In the next room was a man singing. In the room after that, there was a dead body. And in a room almost after it a group of women were laughing at us. It was often pathetic to see the anxiety of some people to save an insect from disinfecting fluid.

The mortality has been so small in proportion to the numbers and the pressure of the population and the density of the houses, that it has suggested to some authorities that there may be another severe epidemic. All who have seen the charts of mortality have ascribed the repressions in the mortality to the influence of the sanitary measures adopted. There can be no doubt that the measures adopted have reduced and lightened the mortality. There is no reason except the influence of the measures carried out why in this city more densely crowded than any city in the British Empire the mortality has not been much greater.

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM BUBONIC PLAGUE BY SECTIONS DURING 1896.

Sections.	Population by Census of 1891.	No. of Deaths from Bubonic Plague.	Rate of Mortality per 1,000 of Population.

Total	821,764	1,936	2·36

Up to the end of 1896, the highest mortality from bubonic plague had occurred in Mandvi, 308 deaths having been registered, equal to a mortality of 8·25 per 1,000, while in Kamathipura the death-rate was 7·77, Middle and Lower Colaba 5·65, Dongri 3·13, Dhobi Talao 2·75, Mazagon 2·76, Kumbharwada 2·57, and 1st Nagpada 2·42. The lowest mortality was registered in the Esplanade, ·09. Yet this section joins Mandvi on the north and is separated by only the Carnac Bunder Bridge Road. It is interesting that, although in the Esplanade on the Mandvi side there are chawls occupied by numbers of low-castes, amongst others, the Municipal scavengers, working in Mandvi, the disease had not spread to the locality. It will also be observed that in the north of the Island, only 5 cases had occurred in Sion on the East, and 12 in Mahim on the West, while further south in Parel the disease was advancing, and 23 deaths had occurred. In the district immediately on the city side of Mahim, *viz.*, Worli, 41 deaths had occurred. If we go to the west side of the Island, we find that in Chaupati only 7 deaths had occurred, while further west in Walkeshwar and Mahalakshmi only 5 and 7 deaths had been registered.

The mortality in Mandvi commenced to decline in the end of October, but the progression of the disease was observed to continue westward, southward and northward.

The table showing the mortality by sections read with the diagram,* exhibiting the order of the occurrence of the first cases, shows the steady progression of the disease from east to west and from south to north. It may be observed that to the extreme north and to the extreme west of the island, the disease had only spread by the end of the year. The gradual progression of the disease seems to have been due to the migration of rats. There is no other explanation that occurs to me, for, had the disease followed the course of the migration of the population, it would at this period have been most general and fatal in the north and west of the island in the localities whither people had migrated in thousands in the beginning of October and in large numbers afterwards. As I have observed before, there was a steady progression in the disease. A movement from the foreshore on the east that seemed to follow the migration of rats from one district to another, as in a garden having many buildings, when the rats are poisoned in one building, they migrate to another, so in the city they seemed to advance when sick from one district to another.

Previous to the appearance of the disease in an epidemic form in Walkeshwar, large numbers of rats were found dead on the paths leading to the hill. They attracted our attention, lying, as they did, in one characteristic position.

It will be observed from the diagram* of the progress of the disease across the Island to the Walkeshwar district that up to a late period, although a number of cases had occurred in the intervening districts and in the same locality of Walkeshwar, the disease had not become epidemic in Walkeshwar, but when that period—the epidemic period as I may call it—in the progression of the disease arrived, and the epidemic had spread across the intervening districts to Walkeshwar and not till then the disease became epidemic in this district. It has to be carefully noted whether there is a direct connection between the sporadic cases and the cases of the epidemic period that appear to follow them at varying intervals. The term incubation applied to the period intervening between the time of the first observed case and occurrence of other cases is very vague.

I have already stated that the highest mortality from Bubonic Plague was registered in Mandvi, 308 deaths out of a total mortality of 1,945, giving a death-rate of 8·23 per 1,000. After Mandvi, Kamathipura suffered most, 227 deaths having occurred, equal to a death-rate on the population of 7·77. Middle and Lower Colaba, which was most affected after Mandvi and Kamathipura, had a mortality of 77 deaths, equal to a death-rate of 5·65 per 1,000. The first cases in Middle and Lower Colaba were labourers in the cotton godowns, and they were going backwards and forwards between Mandvi and Colaba. It is a curious coincidence that the first cases in Mandvi occurred over godowns, and that the first cases in Middle and Lower Colaba occurred in godowns. In Dongri a district adjoining Mandvi the incidence of the mortality is next in severity to Colaba. It is remarkable that it was not higher as the two districts are separated by a narrow road on the north side of which is Dongri, and the south side of which is Mandvi with high and crowded houses on either side. From the beginning people were going backwards and forwards from Mandvi to Dongri and from Dongri to Mandvi. The labouring classes in Mandvi moved about constantly from houses where cases occurred. A very remarkable instance of immunity was observed in the case of the Common Jail in the Mandvi Ward, not one case occurred in this Jail, amongst over 300 prisoners although the buildings are in the centre of an infected area.

From the table showing the mortality by class, it will be seen that amongst the large communities, with the single exception of Jains, the mortality up to the end of 1896 had

---

* Not re-printed.

not risen above 2·91 per 1,000. It will also be observed that, with the exception of Europeans, the mortality was lower amongst Mussalman than in any other large class. The death-rate amongst Europeans was ·08 per 1,000, and amongst Eurasians ·92, only 4 deaths having occurred in the latter community.

The mortality amongst Jains is unequally distributed by sex, being 8·69 amongst males and 6·77 amongst females. The inequality in the ratio of sex-mortality amongst Bhatis was probably due to females leaving Bombay and a reduction in the female population. The inequality in the sex-mortality is very great amongst Mussalman, being 1·18 amongst males and ·768 amongst females.

Amongst Parsees the ratio of mortality amongst males and females was more equal than in most other classes.

TABLE SHOWING THE NUMBER OF DEATHS FROM BUBONIC PLAGUE IN DIFFERENT CLASSES AND THE DEATH-RATE PER 1,000 OF POPULATION IN THE YEAR 1896.

CLASSES.	Males.			Females.			Persons.		
	Population.	No. of Deaths.	Rate per 1,000.	Population.	No. of Deaths.	Rate per 1,000.	Population.	No. of Deaths.	Rate per 1,000.

Total ...	518,093	1,370	2·63	303,671	566	1·88	821,764	1,936	2·53

The mortality by age periods is most interesting. The highest mortality amongst males occurred at two age periods between 10 and 20 and 25 to 30 years of age, while the highest fatality amongst females occurred from 10 to 14 years of age and from 25 to 29. In both sexes the incidence of mortality was lowest under 5 years of age. It is possible that the low mortality at early periods of life may have been due to imperfect registration and not merely to the concealment of cases but to the difficulty of recognition in cases amongst children.

The mortality at nearly all periods of life was lower amongst females than males.

Digestive Diseases of the System.—The mortality from the diseases of the digestive system is 614 more than in the last year and 632 more than the average of the last five years. Of the deaths from diseases of the digestive system, 1,613 were ascribed to diarrhœa, being 425 more than in the last year and 381 more than the average ; and 737 were referred to dysentery, being 112 more than in the last year and 133 more than the average. To all other diseases of the digestive system 755 deaths were ascribed, being 77 more than in the last year and 118 more than the average.

Diseases of the Respiratory System.—From diseases of the respiratory system 5,334 deaths were registered, being 769 more than in the last year and 638 more than the average. Of the deaths from diseases of the respiratory system, 3,021 were referred to bronchitis, being 389 more than in the last year and 127 more than the average. 1,590 were referred to pneumonia, being 236 more than in the last year, 424 more than the average.

Diseases of the Nervous System.—From diseases of the nervous system 2,272 deaths were registered, being 228 more than in the last year and 11 more than the average.

Births.—During the year 15,890 living and 1,598 still-born births were registered, being 206 more than in 1895. Of the living births, 8,267 were males and 7,623 females. The proportion of males to females by the census of 1891 was as 170·60 to 100, and assuming that there were 100 females to 100 males, the birth-rate would be equal to 32·97 per 1,000 of population. This is the largest number of births registered since 1889.

APPENDIX.

No. 1.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER with the GOVERNMENT of INDIA for 1896.

The year, in general terms, was one of unusual heat and deficient rainfall, the latter no doubt contributing to the production of the former. During the monsoon period, which was characterised by a rainfall more or less steadily in defect, the temperature was above the normal; whilst preceding the setting-in of the monsoon, which was late in its arrival, and following its early cessation in September, the heat was excessive. The tracts of country in Southern, Central, and Northern India chiefly affected by these conditions of unusual heat and scanty rainfall suffered, more especially towards the end of the year, from failure of crops, high prices and consequent privation. Mortality was in excess of the average for the preceding five years during the first nine months, and greatly less than the average during the last three months of the year. The lessened mortality of the last three months is no doubt rightly attributed to their unusual dryness and the consequent decrease of malarial diseases.

2. *European Army of India.*—The year 1896 was healthier than its predecessor. The ratio of constantly sick was 94 and the same in both years; but the ratios of admissions into hospital and of mortality show a considerable decrease in the year under report, having been 1,387 and 14·84 respectively, as compared with 1,462 and 15·26 in 1895. The loss to the Army, on the other hand, from invaliding rose from a ratio of 39 in the two preceding years to a ratio of 43 per 1,000 of strength. As usual, venereal diseases and ague were the chief causes of admission into hospital, the former accounting for 37 per cent. and the latter for 17 per cent. of the total sickness from all causes. As usual, also, enteric fever was the most fatal disease, no less than 43 per cent. of the total number of deaths having been due to this cause alone. No other disease was the cause of so much invaliding as secondary syphilis. The total number invalided during the year was 1,966; and of this number secondary syphilis accounted for 448. The diseases which most closely followed secondary syphilis as causes of invaliding were debility, which accounted for 184, and tubercle of the lung, which accounted for 141 cases. In reviewing the provincial Sanitary Reports we found that the months of greatest sickness amongst the general population in 1896 were not, as is usually the case, the last but the first months of the year. So, likewise, in the case of the European Army, the month of maximum sickness was not September, the month of maximum sickness in the five-year period 1890–94, but the month of January. The explanation given of this transfer of greatest sickness from the end to the beginning of the year is doubtless applicable both to Europeans and Natives. The early cessation of the rains, and consequent dryness of the latter months of 1896, would account for diminished sickness and mortality from diseases of malarial origin; whilst the unusual prevalence of influenza and pneumonia would account for the increase of sickness in the beginning of the year. The mortality from these latter diseases, it is true, were mainly attributed to fever in the returns for the native population; but good reasons were given by some of the provincial Sanitary Commissioners for their belief that deaths really due to influenza and chest affections were recorded under the head of fever.

3. Of the different Commands, Bengal gave the highest death-rate during the year, whilst the death-rate of Madras was about half that of Bengal, and the lowest of all the Commands; in the former it was 18·70 and in the latter 9·79. It is disappointing to read that "the percentage of "enteric fever to total admissions in 1896 was greatest in the hills." No less disappointing is it to find that the highest death ratios in large garrisons with a strength of over 1,000, were recorded in Allahabad, Fyzabad, Lucknow, and Agra, when it is remembered that in all of these, excepting Fyzabad, there is a supply of filtered pipe water. In Allahabad the ratio of mortality was "more "nearly four than three times higher" than during the preceding year. The cause of this great increase was enteric fever. Referring to Table V., which gives an abstract of the cantonment Sanitary Reports of the most unhealthy stations, it is found stated that "enteric fever broke out in "the 1st Norfolk Regiment in February, and lasted till the end of April, and again re-appeared "towards the end of December. On both occasions the filter beds of the municipal water-supply "were found to be infected with the enteric microbe." It is added, "the quality of the water is "excellent, except for the finding of the enteric microbe on two occasions." It would have been useful to have been assured that the microbe had been searched for but shown to be absent from the filter-beds during the rest of the year. It can hardly be believed that the microbe continued to exis. in the filter-beds from February until the end of April. If it was looked for and found when enteric fever first showed itself in February, it may be assumed that measures were adopted without delay to cause its disappearance from the filter-beds, or that the source of the water-supply for the regiment was changed, or the water boiled before use. It was confidently predicted by many that the introduction of a filtered water-supply for the use of garrisons would be followed, if not by the disappearance of cholera and enteric fever, at all events by a marked decrease of both. In Fyzabad

the water is drawn from covered wells "which cannot easily be contaminated." In Agra, Allahabad, and Lucknow water is supplied in all three from the municipal waterworks. In the case of the two former, enteric fever is credited to the water thus supplied, but in Lucknow, "it has not been "possible to trace the cause of enteric fever in particular instances, but every year shows how readily "the water, milk, cheese, and other articles of food can be contaminated by the enteric bacillus, "chiefly through the filthy habits of the natives (cooks and others) with whom the soldier is brought "in contact."

4. *Principal Diseases.—Influenza*, which was prevalent in the end of the preceding year, reached its maximum in January of the year under report. In that month 262 admissions into hospital were due to it, whilst the total admissions for the year were 808, or equal to a ratio per mille of strength of 11·5. The months of greatest influenza prevalence, taking the average of the years since 1890, were March and April, and of least prevalence August and November. There were eight deaths from the disease, and a ratio of 61·03 constantly sick. Influenza has thus become a not unimportant cause of sickness and mortality amongst the troops.

5. *Cholera* was more prevalent than during the preceding year, but the mortality caused by it was less than the average for the decennium 1886–95. The attacks numbered 70, or one for each 1,000 of the strength of the Army, and of those attacked only seven recovered. The stations which suffered most were Poona, Benares and Jhansi. In Table V. no account is given of Poona, but of the outbreak at Benares it is said, "cholera is always more or less epidemic. No particular cause could be assigned "for the outbreak in March." At Jhansi there were 10 cases in the months of March, April, May, and July. Regarding this outbreak it is stated, "cholera, which was imported, was unusually "prevalent. The infantry suffered more in consequence of the disease being brought by recruits "joining the regiment from England." Notwithstanding the confident assertions of many writers that cholera is caused by the *comma bacillus*, we find the following to be the latest pronouncement by the Sanitary Commissioner with the Government of India, based on his examination of the evidence recorded by some of the most distinguished bacteriologists who have devoted themselves to the study of this disease :—"The statement that cholera is caused by a particular vibrio must remain "an assumption until the circumstances under which that vibrio is potent to cause cholera have been "discovered." Further, it is added :—"Dr. Klein has frequently isolated genuine vibrios derived "from cases where no connection with Asiatic cholera could be traced." The assertions constantly met with to the effect that the *comma bacillus* is the cause of cholera may well fail to convince when, as the result of Klein's latest researches, we are told that "commas, then, were found in cases "which, clinically and from their antecedent circumstances seemed to justify the exclusion of "cholera from the diagnosis ; and cases occurred in which, clinically and otherwise, the presence of "cholera was indicated, but the commas were absent." Clearly, further research into the etiology of the disease is required before this question of the connection between the *comma bacillus* and cholera can be regarded as finally settled. In India there is never any lack of opportunity for carrying on such research : in the year under report the deaths recorded as due to cholera numbered 471,779 : the number is in some years greater and in some years less. Hitherto, the method of dealing with outbreaks of the disease amongst collections of people which has proved most successful has been the prompt evacuation of the infected locality. As the Sanitary Commissioner puts it :—"Until we know exactly what the cause of cholera is, it is clearly impossible to remove that cause "from a body of men ; but we can remove the body of men from the cause. And movement, in "India at any rate, is the one sovereign remedy : it rarely fails, and when it does fail, the failure "can, generally, be traced to the neglect of reasonable precautions." The two methods of preventing cholera advocated and practised by Mr. Hankin and M. Haffkine are intended, the one to destroy the cause of the disease by chemical agencies, and the other to produce immunity from the disease, in much the same way as immunity from small-pox is produced by vaccination. Mr. Hankin endeavours to destroy the cause of cholera in water, it being the generally accepted belief that cholera is chiefly, if not entirely, a water-borne disease : M. Haffkine by his anticholeraic inoculations endeavours to render the system proof against cholera. Evidence in support of both methods is adduced ; but further experience in their application will be required before they can be accepted as affording effectual protection against cholera, and capable of being applied in practice on an extensive scale.

6. The prevalence and fatality of *small-pox* have been lamentable : there were 122 cases with 10 deaths against 19 cases and two deaths in 1895. Such mortality in a body of men, who may be, and, it is presumed, are subjected to the full prophylactic influence of vaccination, may well lead to inquiry into the cause of the failure of vaccination to protect against fatal attacks of small-pox. Many will still hesitate to accept the conclusion that vaccination is not the efficient protection against death from small-pox which it has hitherto been considered to be ; and will confidently adhere to their belief that where primary vaccination has been efficient, and has in due course been followed by successful re-vaccination, a death from small-pox will be, if not absolutely unknown, exceedingly rare. This seems to be the conclusion at which one of the recent writers on the disease has arrived. The last part of the quotation made by the Sanitary Commissioner from this writer's article on small-pox is here reproduced :—"I have not, however, seen fatal small-pox in any one whose primary "vaccination was efficient, and who also had been successfully re-vaccinated." Some would hesitate to accept the following case as a proof of the insufficiency of vaccination and re-vaccination to protect against a fatal attack of small-pox :—"Bareilly.—Gunner W. had one distinct mark on the right arm. "He had been in 1891 and in 1894 unsuccessfully re-vaccinated. He died of confluent small-pox." Few experienced in vaccination work would consider "one distinct mark" to be a satisfactory proof of efficient primary vaccination. With regard to the failure on two occasions of re-vaccination, it would have been interesting to have been told, whether the lymph used was taken direct from the calf or the arm, or whether it was preserved lymph, and if so, for how long and in what way it had been preserved. The sickness and mortality arising from small-pox during 1896 would seem to suggest the need for an inquiry into the question of the efficiency of the system adopted for the protection of the Army in India against small-pox by means of vaccination.

7. As in the case of the general population, so in that of the Army, there was a marked decrease in the prevalence of ague. The admissions fell from 336 per thousand of strength in 1895 to 239 in the year under report. This decrease was no doubt due to the year having been "the driest on "record," and to the consequent diminution of malaria. The following quotation from the report before us is significant of the difference of opinion and practice still prevailing amongst medical officers with regard to fevers in India:—"Medical officers sometimes note that cases returned as "simple continued fever may have been mild cases of enteric fever; and they differ in practice as to "where they draw the line between simple continued fever and enteric fever, as well as between "simple continued fever and ague."

8. *Enteric fever* continued its destructive course with little substantial abatement. There were 1,795 admissions into hospital and 445 deaths, against 1,870 admissions and 447 deaths in the previous year. As compared with the decennium 1886–95 there was no decrease. The ratio of deaths per 1,000 of strength was 6·31 in the year under report: 6·72 in the preceding year; and 5·2 for the decennium 1886–95. It must be allowed, therefore, that however great the advance which has been and is being made in our knowledge of the etiology of enteric fever, the application of this knowledge to the prevention of the disease has hitherto been productive of little appreciable effect. Believing, as most do believe, that the drinking water is generally the medium through which the human body becomes infected, attention has chiefly been directed to an examination of the water in use when there has been an outbreak of the disease, and to the adoption of measures for securing a supply guaranteed by bacteriological and chemical tests to be free from pollution. It might be supposed that, when the ways of entrance of infection into the body had been traced and narrowed down to a single avenue, the exclusion of the disease, if a constant watch were kept over this avenue, would be possible. But this has not been found to be the case. The reports of medical officers show much difference of opinion regarding the effect of the means used to purify the water at different stations. Numerous instances of this might be given, but it will suffice to quote from some of the abbreviated reports on pages 31, 32:—"Dinapore.—All the wells in cantonments were "disinfected with the permanganate of potassium during the month of April, and the cisterns in "which the drinking water is kept after being boiled are cleaned out once a week with the "permanganate of potassium. The effect of boiling the water has been very remarkable in checking "the number of admissions from enteric fever and dysentery." Again:—"Benares.—During January, "February and the greater part of March the water used was from the wells in cantonments. There "were during that period no enteric fever cases. On removal into sanitary camps, the water was "carefully boiled. Enteric fever from that time became nearly epidemic. On the return of the men "the water was obtained from the municipal waterworks, and was also boiled, but without affecting the "prevalence of enteric fever in the least." The report from Lucknow, after stating that Mr. Hankin found the enteric microbe in four out of six samples of water taken from different standposts in cantonments, goes on to say that, although the microbe was thus shown to be present in the cantonment mains during September and October and to be widely diffused, "there was no corresponding "increase, but rather a marked diminution in the number of cases as compared with the earlier "months of the year." The report concludes:—"From the above data one of two conclusions seems "inevitable, either that the microbe found was not the special cause of enteric fever, or that the "microbe can be consumed with impunity by all but a very small percentage of people." The effect of the permanganate of potassium on the microbe would not seem to be destructive, if the observations made at Agra are to be relied on, "the microbe was also found in a flourishing condition in the pink "water in the receptacles used for holding the drinking water both in hospital and barracks, although "every care was taken and the permanganate solution introduced at night, so as to secure the "necessary effect." Apparently in despair of excluding the cause of enteric fever by sanitary measures, one Medical Officer writes:—"Nothing but inoculation of every young soldier with "preventive serum will, I believe, stamp out enteric fever from the Army. Sanitation, pure and "simple, applicable as it is only to certain limited areas and under the most favourable place—time "conditions, has failed, and, I am convinced, will fail to extinguish the disease."

9. *Venereal disease* continued to prevail with about the same severity as during the previous year. The admission rate was 511·6 per thousand of strength as compared with 522·3 for the preceding year. There was some decrease of admissions from primary, and a great increase in the admission rate from secondary, syphilis. The latter was the highest on record. As with enteric fever, so with venereal diseases, the influx year by year of large numbers of young soldiers under the short service system has been accompanied by a marked increase of both diseases. The Sanitary Commissioner shows that, as the proportion of young soldiers has increased and the proportion of married soldiers has diminished the venereal ratio has gradually risen. There were equivalent to over three regiments constantly sick in hospital from venereal disease. The increase in the prevalence of secondary syphilis is of specially ill omen, "this is a condition of things sure to tell when the men have to go on field service."

10. *Native Army.*—The health of the Native troops was better than during the previous year. The constantly sick decreased from a ratio of 30 to 29 per thousand of strength; and there was a marked decrease in the ratio of deaths. This last, which was 15·71 in 1895, fell to 12·57 in the year under report. The improvement is attributed to the dry and non-malarious character of the year. At the same time, the admission rate from ague, which was 36·21 per mille in 1895, continued to be 36·22, or practically the same in both years. As in previous years, the contrast between the European and Native Armies in respect of the incidence of the diseases to which mortality was due is striking. Of every 100 deaths in the European Army, 43 were caused by enteric fever; whilst in the Native Army only a fraction, 0·4, of every 100 deaths, was due to this disease. On the other hand, the number of deaths in the European Army from pneumonia amounted only to 4·3 of every 100 deaths from all causes; whilst in the Native Army the number was 30·8 out of every hundred. So with Remittent fever, of every 100 deaths in the European Army from all causes, 2·7 were due to this disease; whilst in the Native Army the number in every 100 was 10·5. No satisfactory explanation has hitherto been given of the almost complete immunity of the Native

soldier from enteric fever. The assertion which some medical officers are in the habit of making that the majority of Native children have attacks of enteric fever which confer immunity from further attacks during the rest of their lives, has never been supported by a record of cases of the disease amongst Native children, and seems to be merely a hypothesis invented to account for an immunity which is not understood. The greater liability of the Native than of the European soldier to respiratory diseases is no doubt accounted for by the fact that the latter is better fed, clad, and housed.

11. From influenza, cholera, and small-pox the ratios of admissions did not widely differ in the two Armies. From the first of these they were almost the same in both, having been 11·5 in the European and 10·7 in the Native Army. From cholera the admission rate was identical in both Armies, although the death-rate was somewhat higher amongst European than amongst Native soldiers. Contrary, however, to what might have been anticipated, both the admission and the death-rates from small-pox were higher in the European than in the Native Army.

12. Of the prevalence of *Scurvy* in the Native Army, the Sanitary Commissioner, after showing that the regiments on the frontier, where vegetables are grown with difficulty or are hard to procure, are most afflicted by scurvy, goes on to say :—"But the amount of scurvy existing is far greater than "the amount returned, and medical officers who have not returned many cases of scurvy frequently "refer to the existence of a more or less wide-spread scorbutic taint in their regiments." His advice in this connection is deserving of the attention of all concerned with the maintenance of the health and efficiency of the Native Army :—"No pains should be spared to eradicate scurvy completely, "either by securing an adequate supply of good vegetables, or by increasing the amount of the "ordinary diet and providing variety in the ingredients; because it underlies a vast amount of "sickness that does not directly bear its names."

13. The sickness and inefficiency from *venereal diseases* amongst the Native troops remain much the same from year to year. The admission rate due to them was 37·1 per 1,000 of strength, as compared with 511·6 in the European Army. "Those Native troops that are serving far away from "their homes, and are separated from their families, appear to be most affected by venereal disease, "and several medical officers notice it. The Gurkhas are the most conspicuous example of this. "Some medical officers notice that venereal disease is most frequent among recruits and young "soldiers." Of the 24th Madras Infantry at Quilon it is reported that the restrictions placed on marriage, and the consequent increase in the number of bachelors, have produced a rise in the amount of venereal disease. From such facts it may be concluded that the special conditions which are known to have led to the disastrous increase of venereal disease in the European Army have a tendency to produce a similar effect in causing its increase in the Native Army.

14. *Jails.*—The ratios of admissions into hospital, and of the constantly sick would indicate that the year, as regards prisoners, was a comparatively healthy one. The admission rate per mille of strength fell from 1,082 in the previous year to 983 in the year under report; whilst the constantly sick-rate fell from 44 in the former to 41 in the latter. The death-rate was practically the same in both years. The average annual strength of prisoners was higher than in 1895, a consequence of the scarcity which prevailed, more especially towards the end of 1896. It might have been expected that the effect of scarcity, by sending numbers of ill-fed persons to jail for petty thefts, would have been to raise the sick and death-rates; but this effect was more than counterbalanced, in the jails of India as a whole, by the abnormal dryness of the year and the consequent diminution of malarial diseases. Where, however, scarcity amounted to actual famine, as in the Central Provinces, the returns show that the proportion of prisoners to population increased from a ratio, per 1,000 of the latter, of 4·6 in 1895 to a ratio of 5·2 in 1896; and that the mortality in the jails rose from 55·95 in the former year to 72·36 in the latter. Consequent upon a series of years of bad harvests in the Central Provinces, the jail sick and death-rates are measures of the state of health caused by the privations to which the outside population were subjected, rather than of the good or bad hygienic conditions prevailing in the jails. If a jail is filled with ill-fed, emaciated prisoners, the death-rate will be high, however excellent the hygienic state of that jail may be. And the same cause which in times of famine enfeebles the people of a country will probably send them to jail in numbers so great that overcrowding is likely to result, with the ill effects on health arising therefrom. Such overcrowding prevailed in the jails of more than one of the provinces afflicted by scarcity or famine in 1896.

15. The high rate of mortality from bowel complaints amongst prisoners as compared with the rate in the European and Native Armies has been noted from year to year. "Taking the mortality of the "Native troops from bowel complaints as 1, that of the Europeans is 1·2, and that of the prisoners "14·1." Likewise, with regard to deaths from respiratory diseases; whilst the Native suffers greatly more than the European Army, the prisoners suffer more than both. "Taking the mortality of the 'European troops from respiratory diseases as 1, that of the Native troops is 4·8, and that of the "prisoners 6·9." As concisely put by the Sanitary Commissioner, "the chief cause of death among "European troops was fevers, among Native troops respiratory diseases, and among prisoners bowel "complaints."

16. *Summary.*—Generally speaking, the year was one of unusual heat and deficient rainfall. Failure of crops and high prices, more especially towards the end of the year, caused much privation in some provinces; but the abnormal dryness and consequent diminution of malarial diseases tended to neutralize the effect of these influences on the death-rate. Judging from the decreased rate of admissions into hospital and of mortality, the European Army of India was healthier than during the preceding year, but there was a considerable increase in the ratio of invaliding. Of the Commands, Bengal gave the highest death-rate during the year, and Madras the lowest, the rate for the latter Command having been little more than half that of the former. Influenza in the early months was a not unimportant cause of sickness, and cholera was more prevalent than in 1895. The number of attacks from the latter disease was 70, and all proved fatal except seven. Another year's research has

done little to advance our knowledge of the etiology of cholera, although India continues to afford ample opportunity for its study, nearly half-a-million of deaths having been recorded as due to it during the year under report. In point of efficiency in cutting short an outbreak of cholera amongst the troops, no remedy has hitherto been found equal to withdrawal from the affected locality. Small-pox has been unusually prevalent and fatal, 10 deaths having resulted from this so-called preventible disease. Such mortality seems to suggest the need for special inquiry into the efficiency of the system of vaccination in force for the protection of the European Army against small-pox. There was a marked decrease in the prevalence of ague, due no doubt to the year having been the driest on record. Enteric fever pursued its destructive course without substantial abatement. There is much conflict of opinion amongst medical officers as to the most efficacious method of purifying the water-supply, the medium by means of which, it is generally believed, the disease obtains entrance into the system. Venereal diseases continued to prevail with much the same degree of severity as in recent years. An especially unfavourable feature of the returns is the increase in the number of men shown to be affected with secondary syphilis. Of the Native, as of the European, Army the health has been better than during the previous year. The almost complete immunity of the Native troops from enteric fever, and their comparative immunity from venereal diseases, continue to be marked. On the other hand, chest affections were, as usual, greatly more prevalent and fatal amongst the Native than amongst the European troops, and were accountable, amongst the former, for a large proportion of the year's mortality. Prisoners, as in previous years, suffered more than either European or Native troops from bowel complaints. In parts of the country, such as the Central Provinces, in which the harvests had failed for a series of years, and the people had suffered much from privation, the death-rate amongst the prisoners was very high.

12th October 1898.

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bengal for 1896.

The meteorological features of the year were abnormal. The rainfall was scanty, unseasonable, and irregular in its distribution, resulting in failure of crops and wide-spread scarcity which deepened into famine, and affected a population of upwards of 13 millions. The temperature was high in February, March, and April, as well as in the extreme west of the province in May: the mean continued during the third quarter generally above the normal almost over the whole province, especially in North Bengal and Bihar. In the last quarter it was almost constantly hotter than usual in the day-time throughout October and November. What between the scarcity due to short or unseasonable rainfall pressing hard upon the poorer classes and weakening their resistance to disease, unusually high temperature for the greater part of the year and deficient and impure water-supplies consequent on drought, it was no more than was to be expected that the public health would suffer. Although it can hardly be said that there was anywhere famine owing to actual want of food, prices rose so high as to place it beyond the means of the poorer classes to purchase enough to keep themselves and their dependants in health. The resources of the State had at length to be employed, and distress relieved through the agency of a special establishment, and at the cost of a vast expenditure of money. Owing mainly to these causes, 1896 was an unhealthy year.

2. *Vital Statistics.*—The recorded *birth-rate* rose from 34·59 during the preceding year to 38·03, and the *death-rate* from 31·39 to 34·17. These are still, doubtless, below the actual rates; but they show that registration in Bengal is steadily improving, and give promise that in a few years, if progress is maintained, birth and death statistics will afford fairly accurate information regarding the health conditions of the people of the province. The Sanitary Commissioner thinks that there are good reasons for believing that the actual birth and death rates in Bengal are not much, if at all, below the estimated ratio of 51·8 per thousand of population in the case of the former, and 44 in the case of the latter.

3. Whilst the registration of births and deaths is rapidly improving in Bengal, it is not always quite easy to say, when the numbers of these are seen to increase, how much of the increase is due to the fact that fewer omissions have been made from the registers, and how much to greater fecundity and greater mortality. That the year 1896 was more unhealthy than its predecessor there can, however, be no question. "Not only do the figures show this," writes Dr. Dyson, "but the fact is borne out by the personal observation of district officials "and myself." Cholera and fever were more than ordinarily destructive of life, the former being credited with a death-rate of 3·19 against 2·49, and the latter with a rate of 24·76 against 22·99 in 1896. The causes which led to the increased prevalence of these diseases are believed to have been chiefly those already mentioned, abnormal meteorological conditions and scarcity following crop failures.

4. The incidence of these two chief causes of mortality was different in towns and in the country. Whilst fevers were greatly less destructive in towns than in the country, the contrary was the case with regard to cholera. The ratio of fever deaths was only 19·04 in towns, whilst it was 25·06 in the country. Cholera, on the other hand, is credited with a mortality ratio of 5·14 in towns as compared with 3·09 in the country. The greater prevalence of fevers in rural as compared with urban Bengal is attributed by the Sanitary Commissioner to the almost

entire absence of drainage and to the bad water-supply in rural areas. It might also be suggested that diseases may be somewhat more accurately differentiated in towns than in villages, in proportion to the higher level of education and intelligence of the towns people as compared with the rural population.

5. As children are more sensitive and succumb more readily to unhealthy influences than adults, the ratio of mortality amongst them may be taken as a useful measure of the healthiness or unhealthiness of a season. Infants under one year of age died at the rate of 222·34 per thousand in 1896, as compared with a rate of 195·50 in the previous year. Children of one year and under five years died at the rate of 45·47 and of 40·81 in these two years respectively.

6. *Chief Diseases.*—"In a year of scanty rainfall, irregularly distributed, it is only to be "expected that the mortality from *cholera* will be high, because there is no water to flush out "polluted tanks and wells, which are the chief sources of the water-supply of the people of "Bengal." So writes the Sanitary Commissioner; but an examination of the diagram inserted between pages 24 and 25 of his report would seem to furnish exceptions to his conclusion, that during the past year of scanty rainfall cholera mortality was high when there was no water to flush out polluted tanks and wells. If, for example, the portion of the diagram referring to the Chota-Nagpur Division is looked at, it will be seen that the four months of greatest cholera prevalence, May, June, July, and August, were also the months of heaviest rainfall. In the Orissa Division, also, it will be observed that, whilst there was heavy rainfall in June and July, followed by still heavier in August, cholera not only did not subside but increased during the latter month, the mortality caused by it rising from a ratio of 0·22 in July to 0·4, or nearly double, in August. It would have been interesting to have had the Sanitary Commissioner's opinion regarding the prevalence of cholera in Calcutta and other towns supplied with pipe water. Looking at the returns of cholera for Calcutta, it appears that the ratio was very high, 5·06, and yet the water-supply may be assumed to be to some considerable extent constant in quantity and quality, whatever the nature of the season. However, in all the districts in which cholera prevailed with greatest severity the local officers, it is stated, ascribed the cause of this severity "to deficient and irregular rainfall, and consequently "a more than usually polluted water-supply." Only in Mozaffarpur, a district in which cholera was more prevalent and fatal than in any other of Bengal, does the Civil Surgeon, Dr. Peck, differ from this conclusion, and give facts to support his opinion that the water-supply was not the cause of the disease. "In the southern and central parts of the district where people were "drinking from stagnant puddles owing to the wells being dry, cholera was not nearly so "prevalent as in the north where the wells were numerous and contained plenty of water, viz., "Sitamarhi sub division and notably the Poopri *thana*, which contributed 4,564 deaths from a "population of 232,114. In the Poopri *thana* the wells are good and numerous and nowhere "in Sitamarhi was the water so low as in Mozaffarpur." The Civil Surgeons had their attention directed by Dr. Dyson during the year to the use of permanganate of potash, lime, and alum for the purification of the water of tanks and wells. "It appears," he says, "from the annual "reports of the local medical officers who tried the experiment, that it had a very marked and "beneficial effect." Some extracts are given from the annual reports of certain Civil Surgeons who carried out this method of water purification. One of these extracts, from the report of the Civil Surgeon of Balasore, runs as follows:—"Tanks which were in infected areas were "disinfected with permanganate of potash, which had a marked effect in checking the disease." The Civil Surgeon of Gya writes:—"From various inquiries I made when on tour I am disposed to "believe that the treatment of wells with permanganate of potash was especially effectual in stopping "the spread of cholera." Evidence of this nature may be interesting but is too general and inexact to carry much weight. Anti-cholera inoculation has been carried out during the year; but until a greater number of inoculations has been performed and the subsequent history of each case carefully traced and recorded, it would be premature to give an opinion regarding the nature of this method of conferring protection against cholera.

7. *Small-pox.*—The ratio of 0·18 deaths from this disease was the same during the year 1896 as during the preceding year. As might have been looked for, the only district in which the disease can be said to have prevailed in epidemic form was one in which vaccination is backward. It is not at all surprising to learn that vaccinators of the *Mali* caste—it is not said if they had been inoculators prior to being entertained as Government vaccinators—in many cases spread small-pox by the practice of inoculation. The latter practice is a more profitable one, and carried on under conditions more congenial and pleasing to the operator than vaccination.

8. Of the total number of 13,388 deaths from small-pox, no fewer than 9,831 occurred amongst children under 12 years of age, and of these 2,805 were under one year. In spite of the prevalence of scarcity and famine, the numbers vaccinated show a substantial increase of 16,574 over the numbers for 1895–96. In the districts in which there was a decrease, the chief causes assigned for this were the inability of the people to pay the vaccinators' fees owing to pressure of hard times, the outbreak of fever, from which the staff of vaccinators, as well as the people amongst whom they were working, suffered, and the lessened numbers available for vaccination in consequence of the unusual number operated on in districts in which small-pox was epidemic during the previous year. The percentage of successful cases rose from 98·39 in 1895–96 to 98·50 in the year under report. The Sanitary Commissioner thinks this ratio incredible, and we are disposed to agree with him. The "dishonest practice" followed by the vaccinators of excluding unsuccessful cases from their returns is not confined to the Province of Bengal. Elsewhere many of the vaccinators at the time of operating write on a slip of paper the names of those vaccinated, and the date on which the operation is performed. When they return to ascertain results they copy the particulars from this slip into the authorised register, omitting the unsuccessful cases. The practice is not easily suppressed, but is not very harmful, especially if the vaccinator repeats the operation in the unsuccessful cases when he comes to ascertain results. Estimating the birth-rate at 40 per mille of the population, the Sanitary

Commissioner calculates that 202·81 per thousand of children under one year of age were protected against small-pox. If Mr. Hardy's estimate of a birth-rate of 51·8 is adopted, this proportion would be reduced to only 149·79 per thousand. Whichever estimate is chosen the proportion is small, and leaves ample susceptible material for the epidemic action of small-pox when that disease breaks out. Animal lymph is superseding humanised lymph in Bengal. Where the former is procurable in sufficient quantity and at a reasonable cost, it removes one of the main difficulties with which the vaccinator has to contend, the difficulty of prevailing on parents to consent to the taking of lymph from the vesicles on their children's arms.

9. *Fever* mortality increased from a ratio, per thousand of population, of 22·99 in 1895 to a ratio of 24·76 in 1896. The ratio for the ten-year period 1886-95 was only 18·83, but this latter was calculated on returns of deaths at a time when registration was much more defective than it now is. As the Sanitary Commissioner observes, it is certain that, under the heading of Fever are included numerous deaths which are really due to other causes. The village watchmen, he says, find it less troublesome to assign deaths to a disease recognised to be everywhere prevalent, and regarding which no further inquiries will be made, than to report them as due to such diseases as small-pox and cholera, outbreaks of which entail constant daily reports and journeys to the police station. Although improved registration may, as suggested, have had some share in the increase of the recorded number of deaths attributed to Fever during the past year, Dr. Dyson writes :—"In a year of abnormal "meteorological conditions such as that under report, when the rainfall was intermittent and the "drying and wetting of the soil alternate, a high death-rate from fever is a natural consequence." The districts in which the disease was most fatal were chiefly those bordering the foot of the Himalayahs, and the "fact that they are more or less subject to the notoriously deadly *Tarai* fever, "probably in a great measure explains the exceptionally high death-rate in them."

10. The scheme for the distribution and sale of quinine continues to make progress. The number of packets of quinine sold during 1896 was 31,867, as compared with 28,530 in the preceding year, or equal to an increase of 1,701,870 grains. The Sanitary Commissioner notices a curious relation which the amount of quinine purchased by the people of the different districts bears to the mortality from fever in those districts. "In Darbangha, where the largest number of deaths occurred, almost the "smallest quantity of quinine was sold. Similarly, in the cases of Muzaffarpur, Gya, and Patna, "where the mortality was high, comparatively little quinine was asked for." Two at least of these districts were severely affected by famine; and as the pressure of hard times was given as a reason why the people were unable to pay to have their children vaccinated, the same reason might perhaps be suggested to explain why they could not afford to buy quinine. Other six districts are mentioned in which there was a large demand for quinine; and the Sanitary Commissioner thinks that "the "demand for quinine is highest in those places where its efficacy is best known and therefore more "generally talked about." The returns bring one significant fact out clearly : the sales of quinine were largest during the months of greatest fever prevalence. Another point noticed in the Government review of the report is that, while the total quantity sold has increased, "there has been a "marked decline in the districts most affected in the failure of the crops." This was no more than was to be expected ; all the money available was doubtless required for the purchase of food, leaving none available for extras.

11. *Bowel complaints* were not unusually prevalent. It might have been expected that an examination of the ratios of mortality due to diarrhœa and dysentery would show these diseases to have been unusually fatal in the districts affected by scarcity or famine. They are of the class of diseases known to be connected with the use of an insufficient or unwholesome dietary. In the districts of the Chota Nagpur Division especially, jungle roots and fruit were largely used in place of grain ; yet, in all of the districts of the Division except one, there is no increase, but some decrease, in the mortality from bowel complaints. In the districts of the Patna Division chiefly affected by famine, the returns show that there was neither marked increase nor decrease of mortality from these diseases.

12. *Sanitary Works.*—Excluding Calcutta, there are 145 municipalities in Bengal, with an income, including the balance from the preceding year, of rather over forty-five and a half lakhs of rupees. Out of this income a percentage of 52·79, or more than half, was expended on sanitary works (original and recurring). Water-supply absorbed nearly ten lakhs, and drainage about a lakh and a half. These sums seem small when what remains to be done to provide so many municipal towns with a good water-supply and efficient drainage is taken into account. Referring to the statement given on page 49, it would appear that, leaving out Calcutta, only seven or eight towns have a pipe water-supply ; whilst still fewer possess an efficient drainage system. In the same statement an attempt is made to show, as far as statistics are available, the influence which the execution of these water and drainage works have exercised on the public health. Unfortunately, the inaccuracy of the statistics of past years renders the statement for the most part inconclusive; but the Lieutenant-Governor in his review of the Report says :—"So far as it goes it shows that the public health "has usually improved where large schemes for the improvement of drainage or water-supply have "been carried out." It should not, however, be overlooked that the two forms of sanitary improvement mentioned are complements of each other; and that their beneficial effects on the public health need not be expected to be very marked until they are combined. The case of Bombay is a good illustration of the need for an efficient drainage scheme to accompany the introduction of a water-supply into a town. The most important sanitary works of the year were "the completion of "the Howrah water-supply, additions to the Serampore and Jalpaiguri drainage works, and the "construction of drains and the improvement of the water-supply at Bhagalpur." The Lieutenant-Governor is gratified to see that the total amount contributed by private individuals rose from Rs. 1,88,875 to Rs. 4,94,131.

13. Dr. Dyson has nothing to add to his remarks in last year's Annual Report on the subject of rural sanitation, except that there has not been much real progress in this direction during the year under review. What measures of improvement have been carried out will be found described

in Annual Form No. II. of Appendix I., a statement which covers 131 pages. An effort is being made by the Sanitary Commissioner to work this lengthy statement into a valuable Sanitary record of each registering area, " but it is a very difficult matter to do so, because the information furnished " by the local officers with regard to defects in drainage, water-supply, and conservancy are so general " and meagre as to be of very little use."

14. During the closing months of the year a panic was created by a report that Bubonic Plague had appeared in Howrah and Calcutta. A Medical Board examined the evidence on which the report was founded, and were satisfied from the clinical symptoms that none of the persons affected were suffering from true Plague. The diagnostic evidence based on the alleged presence of the Plague bacillus in the blood of those affected was shown by Dr. D. D. Cunningham to be worthless.

15. Briefly, the year was one of abnormal meteorological conditions. The rainfall was scanty, unseasonable, and irregular in its distribution. As a consequence, there was serious failure of crops, followed by scarcity deepening in many parts into famine. The short rainfall and great heat caused in many places a scarcity of water. Cholera and fever were both very prevalent, and between them were chiefly accountable for the increase in the death-rate. The Sanitary Commissioner attributes the severity of the cholera epidemic to the insufficiency and badness of the water-supply. Neither small-pox nor bowel complaints were unusually fatal, although the latter are generally intensified by scarcity of wholesome food, and such scarcity widely prevailed during the year. Considerable sums of money were expended on drainage, and in providing good water-supplies for municipal towns. Rural sanitation has made but little progress during the year, a result little to be wondered at when the vastness of the task and the slenderness of the means available for its execution are taken into account. A panic, due to a report that Plague had appeared in Howrah and Calcutta, subsided when it was shown by a Medical Board that the persons affected were not suffering from genuine Plague, and that the evidence on which the report was based was worthless.

12th October, 1898.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the North-Western Provinces and Oudh for 1896.

The most marked meteorological features of the year were deficient rainfall and abnormally high temperature. The influence of these on the public health is reflected in the vital statistics. Short rainfall was followed by failure of crops, high prices of food, privation and lessened power of resistance to disease. The first half of the year was a period of unusual heat and drought during which the mortality, under the debilitating influence of privation, rose above the mean: the last six months, which should ordinarily be the half of the year of greatest mortality, had its death-rate reduced considerably below the mean, a result which the Sanitary Commissioner, no doubt rightly, ascribes to the unusual dryness which followed the premature cessation of the rains and the consequent decrease of malaria.

2. *Vital Statistics.*—The *births* exceeded the number of those of the previous year by 81,426, giving a ratio per thousand of population of 35·40 as compared with 34·90 for 1895. The latter exceptionally healthy year chiefly influenced the fecundity of the year following it. The number of births exceeded the number of deaths in 1896 by 97,493, this excess representing the natural increase of the population. But, although the birth-rate exceeded that of its predecessor, it was much lower than the decennial mean up to 1890. The Sanitary Commissioner gives the birth-rate calculated on the population numbers of the last census, for comparison with the birth-rate calculated on the population numbers determined by the addition to the census figures of 1891, of the number of births in excess of the number of deaths since that census was taken. Calculated in either way the difference is represented by the fraction 0·75. There are the usual variations in the birth-rates of different districts. The highest rate recorded was 52·76 in Etah, and the lowest, 22·11, in Naini Tal. In municipal towns the variation of the rates was still greater, beginning at a minimum of 26·4 and running up to a maximum of 61·4.

3. The *death-rate* increased from a ratio of 29·13 in the preceding year, to 33·32, but was only higher than the decennial average by a fraction of 0·53. The highest death-rate, 67·40, was recorded in Jhansi, a district which suffered severely from scarcity, fever, and cholera. On the other hand, some of the districts in the east of the provinces, such as Azamgarh, Ghazipur and Ballia, record death-rates of only 22·32, 22·98, and 23·48. The death-rates in towns greatly exceeded those in rural areas, having been for the former 39·11 and for the latter only 32·59. In some of the towns, as for example in Lalitpur and Hardoi, the death-rate was excessive: in the former it was 114·12, and 87·97 in the latter; but it is explained that these rates were swollen by the establishment of poor-houses within the municipalities, and that these attracted persons in an emaciated condition many of whom after a short time succumbed from exhaustion or disease. A table is given comparing the ratios of mortality in the six largest provinces of India. These ratios do not differ greatly in the four provinces of Bengal, the North-Western Provinces, the Punjab, and Bombay. The highest ratio of 34·17 is recorded in Bengal, and the lowest of 31·69 in Bombay. The recorded ratio for Madras is 20·6, an obviously impossible one, due to defective registration. The ratio recorded for the Central Provinces, 49·31, does not err on the side of exaggeration. In all of these provinces, although in varying degrees, crop failure, high prices, and consequent privation prevailed.

The death-rate among children under one year of age in these provinces is given as having been 233·6 as compared with a decennial average of 238·4. Taking into account the health conditions prevailing during the past year, the ratio of deaths amongst infants might have been expected to have exceeded the average.

4. The endeavour to differentiate diseases by a professional agency resulted in the record of 12,633 deaths by persons possessed of some degree of medical knowledge. Of these deaths, 4,727 are recorded as having been due to fevers ; but of this number 4,517 are unclassified. The proportion which deaths from fevers diagnosed by professional agency thus bears to the total number of deaths from all causes, works out to 35·7 per cent. ; whereas the proportion recorded mainly by village watchmen as due to fever is 77·1, or more than double. It follows that, deaths recorded as due to such other diseases as dysentery, diarrhœa, and chest affections constitute a higher proportion of the deaths due to all causes in the returns submitted by professional than in those submitted by unprofessional agencies. This only confirms what was known before, that the village watchman when uncertain as to the cause of death usually records it under the head of fever, and that the numbers under this heading are thus swollen to more than double what they in reality should be. As Dr. Thomson, however, observes with regard to the record of fevers even by professional men, it detracts much from the value of the record to find the bulk of them lumped under the head of " other fevers."

5. Registration of *births* and *deaths* continues to receive much attention. No fewer than 144,049 entries of births and 130,219 of deaths were examined by local district officers. The result was the detection of a percentage of 2·73 omissions of births and of 2·37 deaths from the registers. In addition, 233,027 births and 192,173 death entries were examined by the vaccination staff, who found a percentage of 1·34 of the former and of 0·73 of the latter omitted. The Sanitary Commissioner explains why, in his opinion, the percentage of omissions detected by the vaccination staff is so much smaller than that detected by local officers, and attributes it to the need the former find to be on good terms with the village watchmen, who have it in their power very effectually to assist or obstruct the vaccinators who come to carry on operations in their villages. The vaccinating staff, he thinks, although they do not always report omissions of births and deaths detected in the watchmen's handbooks, generally arrange, in concert with the watchmen, at the time of their inspections, to have the missing entries filled in. The practical result is that registration is improved whilst the vaccination staff do not forfeit the good-will of the watchmen so needful to the success of their vaccination work. Of the value of this system of testing the entries in districts, the comparative accuracy of registration in these provinces is a practical proof. Where such testing is carried out in a perfunctory fashion this is not allowed to pass without notice by the Government. " In the " Mirzapur district, the testing which consisted of an examination of 73 entries was merely nominal " and significant only of failure to comply with the Government orders on the subject."

6. *Chief Diseases.—Cholera* was more prevalent than during the preceding year, yet it cannot be said to have been unusually destructive of life. The number of deaths due to it was greatly exceeded in three of the preceding five years. As usual, the first three and the last two months of the year were those in which the fewest deaths occurred. From having caused only 1,145 deaths in March, it rapidly increased in fatality during April and May until in the latter month 12,480 deaths were attributed to it. In June the number of deaths fell to 9,380, and in July still further to 5,138, again rising to 9,366 in August, and attaining a maximum of 12,926 in September. From this time the disease declined slowly in October, and more rapidly in the next two months, until only 226 deaths were recorded against it in December. It had thus two periods of increase and two periods of decrease during the year. The meteorological accompaniments of this waxing and waning of cholera twice during the season appear to have been as follows :—March was almost absolutely rainless, and the temperature from 2·5 to 3 degrees above the normal. April was very hot, but a considerable fall of temperature occurred about the 18th of the month : it rose again, however, towards the end of the month when it was in considerable excess. Practically, no rain fell anywhere. In May temperatures were everywhere above normal : a little rain fell during this month, but except in the Agra Division the fall was everywhere in defect. Cholera thus attained its first maximum during a period of increasing and abnormal heat, and a period marked by the defect or absence of rainfall. The meteorological features of the period attending the decline of the disease from its first maximum of over 12,000 deaths in May to a little over only 5,000 in July were :—A cool month of June when rainfall was generally in excess of the normal. July was also cool at its commencement : from the 22nd the temperature rapidly rose and was high towards the end of the month. Rainfall was in serious defect in nearly all divisions. During the second rise of cholera in August until it reached its second maximum in September, August was an extraordinarily dry month, and the temperature throughout the provinces was excessive : the light rainfall and the excessive temperature were the general features of the month. In September the mean pressure was above normal, and temperature was much higher than usual : the rainfall for the month was excessively small. During the second decline of the disease—slowly during October and rapidly in November and December—it is stated that October was almost uninterruptedly fine. Of November it is said the temperature was excessive at nearly all stations, and that rain fell on the 21st. In December "the mean temperature of the month was about normal." Briefly, it may be said that the disease attained its first maximum in a period of abnormal heat and dryness ; that it underwent its first decline during a period of rainfall and coolness ; that it reached its second maximum after the cessation of rain and during a period of excessive heat ; whilst it finally subsided during the last three months of the year, the first two of these unusually hot and dry, and the last about normal. The most violent outbreak was in Banda. The Sanitary Commissioner is doubtless right in saying, regarding the consequences of this outbreak amongst the people assembled on the relief works :— " The frightened people adopted a procedure which was probably the best under the circumstances, " and ran away from the infected areas." He adds :—" The water-supply is generally the most active " agent in the dissemination of the disease. In Banda the supply was carefully protected as far as " possible, but water was scanty and the wells were few."

7. *Small-pox and Vaccination.*—From having been in abeyance during 1895, when it was credited with the lowest mortality ever recorded against it in the province, small-pox broke out in widespread epidemic form in the year under review. Whilst only 1,968 deaths were recorded in 1895, the number increased to 42,771 in 1896. This recrudescence of the disease did not come as a surprise. An unvaccinated residuum was known to be accumulating from year to year; and, in accordance with the previous history of small-pox in these provinces, an epidemic outbreak was anticipated. Heavy as the mortality from the disease was, reaching a ratio of 0·91 per mille of the population, it was considerably less than that recorded in 1890, when it was 1·26, and far less than that in 1884 when it was 4·59. Although mortality was greatest, as was to be expected, amongst children, yet a large number of adults succumbed to the disease. In some towns, such as Nehtor with a ratio of mortality of 12·86, and in Aonla of 10·10, the severity with which the disease prevailed leaves little room for doubt that vaccination and re-vaccination are much neglected. The ratio of deaths from small-pox in towns was, however, somewhat lower than in the country, having been in the former 0·86 as compared with 0·92 in the latter. In spite of several circumstances adverse to the progress of vaccination, there was no falling-off in the number of operations, and merely a nominal decrease in the percentage of success in primary vaccinations. The increase in the number of successful primary vaccinations was slight, amounting to only 3,022 cases; but in re-vaccinations it was 16,103. The panic which the outbreak of small-pox causes would account for the greater number of persons submitting themselves to be re-vaccinated. Looking at Statement No. 1 of the Vaccination Report, a noticeable feature of the returns is the surprising percentage of success claimed in re-vaccination. In no fewer than 10 districts, cent. per cent. of the re-vaccinations in which the results were known were recorded as successful; and in the district of Aligarh the percentage is represented as having been 100·57. These figures suggest the need for the exercise of vigilance on the part of the inspecting staff. The mortality from small-pox is not surprising when the returns of vaccination are looked into. Taking the number of births for the province in 1896, and deducting therefrom the number of deaths of children under one year of age, it is found that 1,275,250 remained available for vaccination. Of this number only 578,055 were protected against small-pox by vaccination, leaving an unprotected residuum of 697,195. Examining in the same way the figures for Allahabad, the district in which the highest mortality from small-pox (4·10) is recorded, it will be seen that of a total number of 38,452 children available for vaccination, after deducting the number who died from the total number born, only 9,827 were protected by vaccination, leaving no fewer than 28,625 to feed a small-pox epidemic. Allahabad, the head-quarters district of the Government of the North-Western Provinces, instead of showing an example of enlightenment and progress to the rest of the districts, has ever been one of the most backward as regards vaccination.

8. The ratio of deaths from *Fevers* increased from 23·31 in the previous year to 25·71 in the year under notice. The maximum mortality occurred in December, and the minimum in July. The course of fever prevalence throughout the year is described by Dr. Thomson to have been, with the exception of an increase of the mortality due to it in March, normal until the end of October, although each month recorded a higher mortality from the disease than the corresponding month of the preceding year. After October, the mortality decreased in the following month. "It seems "probable that, on account of the premature cessation of the rains, and the scanty fall, the period of "great fever prevalence had been abbreviated. If this theory is correct, the fall should have "continued through December, but this was not the case; a sharp rise occurred, and the maximum "mortality was recorded in that month." This rise is explained as having probably been due indirectly to scarcity. The privations caused by high prices had reduced the stamina of the people, "and an attack of sickness or fever which would merely have prostrated for a few days a well-fed "person, often proved fatal to an individual imperfectly supplied with food. Cold and wet, too, "would be serious foes to people with little to spare for the purchase of warm clothing—especially "as regards the very young and very old." It is added that most cases of pneumonia would be returned as fever: this has been found to be the case during the cold season in other provinces.

9. Regarding the prevalence of *Bowel-complaints*, it is remarked that there was nothing peculiar, except a rise of mortality from these diseases in December. This rise was only what was to be expected during a time of scarcity of wholesome food. Diarrhœa and dysentery are the almost invariable concomitants of insufficient or unsuitable diet. For the year as a whole, however, the mortality from these two diseases was somewhat less than during the previous year.

10. *Sanitary Works.*—An account is given of the amount and quality of the water supplied during the year to the towns provided with water-works. Generally speaking, the quality of the water was "good." With regard to Allahabad, it is stated, "the supply was generally good, but twice it was "reported that the enteric microbe had been detected in the filters." It is added, "the contamination "was temporary and accidental." A similar case of temporary impurity of the water supplied to Meerut is noted. "The character of the supply is good, though on one occasion, through careless "working of a filter, the number of microbes rose to 3,000 per cubic centimetre." The only new water-works completed during the year were those at Meerut. A statement is given with the object of attempting to show, from vital statistics, the influence on the public health of the introduction of water supplies and drainage systems. It cannot be said that any satisfactory conclusion can be arrived at from an examination of these statistics. Taking the figures on the portion of the statement on pp. 32–33, it will be seen that in rather more than half the number of circles the death-rate shows an increase, and in rather less than half a decrease, since the introduction of a drainage system or water-supply or both. The statement includes a long list of circles in which works of comparatively trivial importance have been carried out; and the Government point out that the statement "should "be confined to large and important works, the construction of which is likely to have a distinct "effect upon the public health." With regard to minor sanitary works, the Lieutenant-Governor also observes that the account given of the measures taken for the sanitary improvement of different places in column 14 of Form No. II., makes it scarcely necessary to give the details shown in paragraphs 78–180. The omission in future of these paragraphs, or better still, the abridgement of Form No. II., will considerably shorten the Report, and lessen the labour of preparing it.

11. Sanitary progress during the year was restricted by the need for employing the ordinary Department of Public Works Establishment in organizing and superintending works in connection with the relief of distress, as well as by the want of funds due to the heavy expenditure on famine relief. The Sanitary Commissioner thinks that, by far the most important measure taken during the year as regards sanitary progress was the issue of the Government Resolution reconstituting the Sanitary Board of the province. This resolution "converts what was practically merely a consultative "body into one with definite powers and funds at its disposal, and places the Department on a sound "scientific basis. It cannot fail to make for good." There is no doubt that, if a sufficiency of funds is placed at the disposal of this Board, sanitary progress will be accelerated. It will, however, perhaps be best to wait for results before expressing a too sanguine prediction regarding the influence which the resolution is likely to exercise on sanitary progress. The wisdom of the instructions given to the Board in the ninth paragraph of the resolution will be questioned by no one possessed of a practical knowledge of sanitation in rural India :—"But here it may be said, for the Board's general "guidance, that they should discourage rules and works which are not of a simple character. No "attempt should be made to introduce the latrine system, and what is done, or attempted to be done, "should be unpretentious, agreeable to the feelings of the people and in general harmony with "existing village practice." If these instructions are attended to, no change of a sudden or revolutionary nature in village sanitation is likely to follow the issue of this resolution, the importance of which the Sanitary Commissioner thinks "it is almost impossible to overrate."

12. *Summary.*—As in most other parts of India, the rainfall in the North-Western Provinces and Oudh was scanty and irregular. Failure of crops, more or less complete, followed; and the poorer classes underwent, in extensive tracts, much privation. But for the timely relief given by the State the mortality due to want of food would, in some districts, probably have been considerable. In spite of State aid, it was inevitable that numbers should have their powers of resistance to disease weakened by privation. Prices of grain compared with the mean of the previous year, when they were also high, rose from 17·3 to 12·7 *seers* per rupee. Cholera and small-pox were more fatal than in 1895, the former disease showing two periods of rise and fall during the year. Fevers were also more fatal, partly owing to the vital stamina of the people having been lowered by privation. The need for the employment of the ordinary staff of the Department of Public Works on duties connected with famine, and to the diversion of funds towards famine relief, retarded sanitary progress. A Resolution issued by the Government reconstituting the Sanitary Board and giving it executive in addition to consultative power is regarded by the Sanitary Commissioner as a measure the importance of which on sanitary progress it is almost impossible to overrate. The remarks on sanitary defects and the remedies taken for their removal given in Annual Form II. are concise and to the purpose. The Lieutenant Governor thinks they render the details given in paragraphs 78–180 scarcely necessary, an opinion with which we agree.

12th October, 1898.

No. 4.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Punjab for 1896.

The climatic conditions, like those of the previous year, were favourable to health. The rainfall was much below the average for the previous 10 years. As a result, although the crops suffered and prices rose, especially towards the end of the year, causing much privation amongst the poorer classes, yet, owing to the diminished prevalence of malarial diseases accompanying unusual dryness of the last months of the year, the death-rate rose little above the rate for the preceding very healthy year of 1895.

2. *Vital Statistics.*—Although the number of births was less by 16,892 than in the preceding year, the *birth-rate* was the highest recorded in any Province of India. Calculated on the census population of 1891, it was 43·04 per 1,000, or a fraction below the ratio for 1895. But high as this rate is, it is still below the actual rate. In some of the frontier districts registration, as shown by the returns, continues to be very defective. In the Peshawar and Hazara districts examples are given of birth-rates being returned by police circles of 11·6 and 17·2 per mille of population. The recorded proportion of 110·1 male to every 100 female children born is high; but tends to diminish with the improvement of registration. Where, as in the Peshawar and Kohat districts, rates of 136·9 and 123·2 males are recorded against every 100 females born, registration is very backward. The excess of births over deaths was 236,593: in other words the population of the province increased by this number or at the rate of 11·5 per mille. Such rapid increase may be taken as an indication of growing prosperity accompanying extension of irrigation and cultivation of hitherto waste land; but if its unrestrained continuance ultimately tends to the conversion of the Punjab into an overcrowded province, of which Oudh, Bihar, and other parts of India may be taken as examples, the prospect can scarcely be regarded with unmixed satisfaction.

3. There was an increase in the *death-rate* from 29·29 in the preceding year to 31·53 in the year under notice, due in part to a severe epidemic of small-pox. As the birth-rate was higher than that of any other province in India so was the death-rate lower, if we except Madras, in which an impossible rate of 20·6 is recorded, and which need not, therefore, be taken into account. The rate varied between 40·9 and 40·4 in the Umballa and Karnal districts, and 23·4 and 22·9 in Gujrat and Dera Ghazi Khan. According to age, the ratios of deaths per 1,000 living were 229·14 of male and 223·32 of female children under one year. "The districts of Jullundur, Ludhiana, Amritsar, and

" Ferozepore, particularly the first two, show an excess of female over male infant death-rates. " Measures are now being taken to prevent the practice of infanticide or deliberate neglect of female " infants in these districts." One of the uses of accurate registration of vital statistics is to attract attention to such discrepancies as those shown to exist between the number of male as compared with the number of female children dying in some districts, and to lead to inquiry being made into their causes. The case of the four districts named also suggests the need for caution in hastily assigning to defective registration anomalies in vital statistics which may have an altogether different explanation.

4. Registration of births and deaths continues to receive much attention in the Punjab, with the result that the ratios of both approach nearer than those of most, if not of all, other provinces to the ratios estimated by actuaries. That there is still room for improvement, however, even in the Punjab, is clearly shown by the results of the testing of entries in the village registers. In 15,111 villages, the registers of which were tested by the Tahsildars and their assistants, 2,089 omissions of births and 1,202 of deaths were discovered. In 338 villages in one district, and in 716 in another, only one omission was discovered by these officials. Regarding this, the Sanitary Commissioner truly remarks :—" Such superficial inspection of the registers is useless." From the registers of 28,444 villages the vaccinators found that 13,326 entries of births and 3,420 entries of deaths had been omitted ; and, the omissions discovered by Divisional Inspectors were still more numerous : these latter discovered that 6,925 births and 3,733 deaths had not been recorded in the registers of the 3,242 villages visited by them. These figures indicate that the duty of testing the accuracy of those registers is carried out with very different degrees of thoroughness by the several agencies employed. Whilst Tahsildars discover only one entry omitted, on the average, from the registers of every five villages inspected, the vaccinators discover one in about every two villages ; and the Divisional Inspectors three in every village inspected by them. Were the only mode of inspecting which can be regarded as effectual, a house-to-house inquiry, carefully carried out, it is more than probable that the number of omissions discovered even by the Divisional Inspectors would be found to be below the reality. But house-to-house inspection takes more time for its efficient performance than hard-worked district officials can bestow. There were 70 persons fined for neglecting to register births and deaths in the municipal towns of the Punjab during the year.

5. *Chief Diseases.—Cholera* was credited with 5,146 deaths, or a ratio of 0·25 per thousand of population, as compared with a mean of 0·85 for the previous five years. With the exception of a single case taken from the train at Ludhiana in April, no case of the disease was reported in the province before the month of May. In the Eastern districts which lie next the North-Western Provinces a few cases occurred in the beginning of May. On the 17th of that month, a severe outbreak of the disease took place in the Rawal Pindi district. Up to the 17th of May, 70 cases had been reported by the Civil Surgeon, who states that "all cases had contracted the disease at the " Nurpur fair." Dr. Bamber could not ascertain how the disease came to the fair ; but says that one of the first cases was a sweetmeat seller, and that he suspected this man spread the disease. The Sanitary Commissioner himself visited Nurpur on the 9th of April, more than a month before cholera broke out there. After describing the mountain stream which usually supplies the place with drinking water, and remarking that it had failed to a considerable extent on account of the dry weather, he says :—" Given a single case, therefore, of cholera in one of the pilgrims and knowing " the habits and customs of the people at wells and watercourses, the epidemic here resolves itself into one of water-poisoning in a wholesale manner." The conclusion thus drawn rests on the assumptions that there was a case of cholera in a pilgrim who visited Nurpur, that this pilgrim infected the water-supply, and that the water-supply spread the disease. The assumptions are neither far-fetched nor unreasonable, but they rest on no basis of ascertained facts.

6. Experiments were continued with the view of testing the protective value against cholera of disinfection of wells by lime, permanganate of potash, and alum. These experiments were carried out in every district in which the disease appeared, and the Sanitary Commissioner writes :—" From " every district where disinfection was tried, the opinion of the medical officer is distinctly favourable " to the system, and in several places the villagers themselves begged to have it carried on when they " saw the results which followed." Such opinion is valuable, and it is supported by the opinion of medical officers in other provinces. At the same time, further experiments, and those conducted in accordance with scientific methods, are required to show in what way and to what extent these agents act in putting a stop to cholera by destroying its cause in drinking water.

7. The year was characterised by a severe epidemic of *small-pox*, which carried off 45,084 people. The death-rate from this disease was equal to 2·19 per thousand of population, a rate which has not been exceeded since 1879, when it was 2·83. There was nothing remarkable about the progress of the epidemic except its unusual severity. It was a continuation of the epidemic which prevailed in the previous year, during the last month of which no fewer than 2,088 persons were carried off by it. As usual, the mortality increased through the hot months until it attained its maximum in May, after which it declined, until it reached its minimum in September. During the last three months of the year it again showed a tendency to increase. As might have been anticipated, the districts which enjoyed the greatest immunity during the epidemic were those, such as Kangra, in which vaccination of the population is the most complete. Accompanying this severe epidemic of small-pox it is disappointing to find from the returns that there was a decrease instead of, as might have been expected, an increase in the number of persons vaccinated during the year 1896-97. The falling-off was chiefly in primary operations ; but under the head of re-vaccination there was also a slight decrease. Ordinarily, an epidemic of small-pox acts as a stimulus to vaccination and more especially to re-vaccination. In the Punjab it would appear to have had an opposite effect. The Vaccination Report has been effectively reviewed by the Government of the province, and, more briefly, by the Government of India ; and it is conclusively shown that the prevalence of scarcity, and of small-pox, and of emigration assigned by the Sanitary Commissioner and the Civil Surgeons as the causes of the decrease in the number of vaccination operations could have had little or

no share in bringing about such a result. At least one of these assigned causes, the prevalence of small-pox, should have had the opposite effect of giving a stimulus to vaccination. In Appendix A. of the Vaccination Report, some statistics are given to show the comparative efficiency of the different descriptions of vaccine lymph used by the special staff during the year. From the figures given in Table No. II. of this Appendix, it appears that human lymph gave considerably the best result, that buffalo-calf lymph came next in degree of success; and that lymph preserved with vaseline was the least successful of the three kinds used. Whilst the percentage of success given by human lymph was 99·09, that given by vaseline lymph was only 95·66. The points discussed in paragraph 10 of the Appendix already referred to are of importance, and raise the vital question of the efficiency, or otherwise, of the protection against small-pox conferred by vaccination with vaseline lymph. Dr. Hunter says:—"It has been objected that the scars after vaccination with vaseline lymph do not "usually present that pitted appearance which some people maintain as the test of a good "scar and efficient protection." No time should be lost in proving, beyond any possibility of question, that the opinions of those "people" are groundless, and that the protection conferred against small-pox by vaccination with vaseline lymph is as thorough and lasting as that following the use of lymph taken direct from the calf or from the arm. Persons vaccinated with vaseline lymph which has not left behind it the pitted or "foveated" scar hitherto generally considered to be characteristic of genuine vaccination, might be subjected to the test of a subsequent operation performed with fresh calf or human lymph: if they failed to respond to either of these, some confidence might be felt in the efficiency of the vaseline lymph. But whatever test or tests may be employed, there should remain no shadow of suspicion regarding the protective efficiency of the lymph used for vaccination.

8. Nearly the same number of deaths occurred from *fevers* as in the preceding year. The ratio of deaths per 1,000 of population from this cause was 19·15 in the year under report, and 19·08 in 1895. Both years much resembled each other in their climatic features, having both been unusually dry, and both characterised by low death-rates from fever. Ordinarily, the last months of the year are those of greatest fever prevalence; but the last months of 1896, the driest year on record, enjoyed an exceptional immunity from malarial diseases. Contrary to experience, the month of January showed the greatest mortality from fever, no fewer than 61,134 deaths having been attributed to it, or nearly twice the number recorded as due to it in any other month of the year. In explanation of this transference of highest fever mortality from the end to the beginning of the year, the Commissioner writes:—"This curious fact appears to be "due chiefly to erroneous classification, for, from personal experience of the province, I feel "satisfied that the majority of deaths reported in January as due to fevers were really caused "by pneumonia and chest complaints."

9. *Bowel complaints* were, as in the case of fevers, less fatal than usual. The diminished mortality from bowel complaints and fever, which characterised the vital statistics of the two successive years 1895 and 1896, is attributed to the unusual dryness of both.

10. *Sanitary works.*—The income of municipal towns for the year amounted to upwards of forty-one lakhs; and the expenditure to over forty-three lakhs. Of the latter sum, nearly six lakhs were expended on conservancy, over a lakh and a quarter on drainage and sewerage, and over a lakh and sixty thousand on water-supply. Considerable activity seems to have been shown in carrying out drainage and water-supply schemes. Part I. of the Delhi Drainage Scheme was completed; whilst schemes for Lahore and other towns are in progress. A scheme for draining the flooded area of the Karnal district was undertaken, and other drainage works of greater or less importance were under consideration or had been sanctioned. Of waterwork schemes, those at Delhi and Umballa were completed, as well as others at Haripur, at the Umballa District Jail, and at Simla.

11. A statement is given with the object of endeavouring to show, by the vital statistics of towns and rural circles, the effect on health produced by the introduction of drainage systems, or water-supplies, or both. Dealing only with towns, it is seen that, of the 17 mentioned in the statement, the death-rate had diminished in seven, increased in eight, and remained the same in the other two. Dr. Roe endeavours to explain these unsatisfactory results. It is unquestionably true that, as he says, "It takes time to accustom the people of any town to the "use of pipe water, and at no time do the people, as a whole, use it exclusively." Under such circumstances it is certain that the influence of water service on health cannot fully be determined. "Another reason," he continues, "seems to be the tendency of late years for the "population to increase in the towns, while the accommodation remains practically the same, "thus leading to overcrowding, and personally I am inclined to consider, in great measure, this "influence as the chief factor in producing the very indifferent results hitherto obtained." Defective registration of vital statistics might be added to the other possible factors concerned in producing these indefinite results. In many towns in other provinces improvement of registration of births and deaths is making steady progress, with the result that, although the actual number of deaths may remain the same or even decrease, the recorded number increases. Improvement in the health of towns which vital statistics would show if registration were accurate, might in this way be masked, or might even be made to appear as deterioration.

12. Village inspection books are being introduced into selected villages. If properly kept up, "it "is hoped that in the course of years they will prove useful in giving important sanitary information "to inspecting officers at the time of their visits to the villages."

13. *Summary.*—The year 1896, like its predecessor, was healthy. Both years resembled each other in being exceptionally dry. Deficient rainfall was followed in some tracts of the province by failure of crops, high prices, and considerable privation amongst the poorer classes. But the healthy characteristics of the year more than counterbalanced the injurious effects of privation on the

death-rate, which remained below the average mean of the previous five years. Registration of vital statistics continues to receive much attention. The birth-rate was the highest, and the death-rate the lowest, recorded in any of the larger provinces of India excepting Madras; and in Madras the vital statistics are so defective as to be useless for purposes of comparison of its health conditions with those of other provinces. Cholera was not excessively fatal, and the mortality from fevers and bowel complaints was much the same as during the preceding very healthy year. But a violent epidemic of small-pox swept off upwards of 45,000 people, demonstrating in an unmistakeable way that the protection conferred upon the population by vaccination is still very incomplete. Considerable activity was shown in the prosecution of sanitary improvements. The endeavour made to show from vital statistics the influence on the health of the people exercised by drainage schemes and the provision of water supplies, failed to lead to any definite conclusion.

12th October, 1898.

No. 5.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1896.

A table is given at page 14 of the report, showing the meteorological and mortuary statistics together with the prices of food-grains for the year in four districts; but we are cautioned not to place too much reliance on indications which this table may seem to afford whilst registration is so defective. It would have been more useful had the Sanitary Commissioner devoted a paragraph to a description of the general meteorological features of the year; to a brief account of the character of the harvests, whether they were abundant or deficient; to a comparison of the price of food-grains with their prices in former years; and to an expression of his opinion as to the influence which these factors exercised on the health of the province.

2. *Registration of vital statistics* continues to receive much attention. That improvement proportionate to this attention has followed is made clear by an examination of the table given on page 8 of the report. From this it will be seen that the recorded birth-rate, which in 1872 was only 17·79 per mille of population, has risen to 32·27 in the year under review; whilst the death-rate within the same period has risen from 12·48 to 23·63. It is pointed out that the ratios of both births and deaths recorded for 1896 are calculated on the census figures of 1891; whilst the increase in the population of the province since the latter year must have been considerable. The consequence is that the ratios are somewhat higher than they would be if calculated on the actual population numbers of 1896. But after making full allowance for this source of error, which probably would not affect the results to more than a fractional degree, the improvement has been marked. It is doubtful if, in Burma, the agencies available for the work of registration are capable of being made so efficient as those in some of the provinces of India. In these latter, the village watchmen record the births and deaths on the spot, and periodically take the record to the police station for entry in the register of the circle. In Burma the headman of a village, or of a town ward, is probably not so well-disciplined or so much under control as a salaried watchman. But after all, the method of working a system is often more important than the system itself. The Lieutenant-Governor truly remarks:—"Deputy Commissioners should give "Civil Surgeons every assistance in inquiring into every case in which the rates of births or "deaths are considerably higher or lower than the average of the surrounding circles. Unless "the headmen and police believe that the Deputy Commissioner is interested in the matter "they will not take any trouble about it." The report is replete with evidence that strenuous efforts are being made to improve registration, the importance of which is fully recognised. As the Government of India, in their review of the report, observe:—"An efficient system "of registration is the surest basis of sanitary improvement and the only reliable warning against "the danger of epidemic disease."

3. The recorded *birth-rate* was 32·27 per thousand of population, as compared with 29·04 in the preceding year, and with a mean of 25·65 for the previous five years. The increase is doubtless due in some degree to the increased population numbers of 1896 as compared with those of its predecessors; but it is probably the result mainly of the omission of a smaller number of births from the registers. The proportion of male to female children born was, for the province, 107 of the former to 100 of the latter; but there are striking variations in this proportion in the different registration circles. The Sanitary Commissioner observes:—"Disparity in the sexes "is usually less pronounced in the circles returning the highest ratios of births." This may be interpreted to mean that where registration is approximately accurate the numbers of male and female children born more nearly approach each other. So constantly is this true, that the degree of divergence or approximation in their numbers may generally be taken as some measure of the accuracy or inaccuracy of the registration. The number of males born to every 100 females varies from 149 in one registration circle to only 71 in another; in the former the recorded birth-rate is 28·09, and in the latter 25·65. Unless special conditions exist in these circles which would account for these low ratios, it would to fair to estimate their actual birth-rates at over, rather than under 40 per thousand of population.

4. The recorded *death-rate* for the province was 23·63 per thousand of population. Except as marking improvement in registration and indicating how much remains to be done before approximate accuracy of the returns can be attained, these figures cannot be regarded as possessing much value. On the contrary, they are apt to be misleading. An attempt is made, in compliance with the orders of the Government of India, to show from vital statistics the influence which the introduction of a drainage system, or water-supply, or both, into towns has exercised on the health of those towns. It is obvious that, if introduced at a time when registration is so defective that little more than half the number of deaths are recorded, the drainage system and water-supply, instead of diminishing, may appear to increase the death-rate as the registration becomes more complete and fewer deaths escape record.

5. *Cholera* is credited with having caused 2,959 deaths during the year. A map is attached to the Report, showing the tracts of the province affected, as well as a statement purporting to record the dates on which the first and last deaths from the disease occurred in the several registration circles and towns. In towns, some reliance may perhaps be placed on these dates, but in rural circles, taking into account the agencies furnishing them, anything like accuracy can hardly be looked for. The Sanitary Commissioner might in future reports briefly describe the conditions which may appear to have influenced the outbreak and spread of cholera, and the effect of the measures, if any, adopted to arrest its progress. In some of the provinces of India much benefit is claimed to have followed the purification of the water-supply by permanganate of potash and other chemical agents. It would be useful to have some record of the experience collected in Burma regarding the influence which the water-supply seems to exercise on cholera prevalence.

6. *Small-pox and Vaccination.*—The number of deaths recorded as due to small-pox was only 814, which gives a ration of 0·37 per thousand of population. In Rangoon city alone, 275 of these deaths were recorded. The propagation of the disease in Burma is supposed to be connected with the immigration from India of unprotected coolies; and proposals for remedying this evil are under consideration. Perhaps the remedy might be found in a measure for securing the vaccination of the coolies at the time and place of their recruitment, or at all events before they land in Burma. Vaccination throughout the province generally, made satisfactory progress. In lower Burma alone, there was an increase in the number vaccinated of 45,536 over the numbers of the preceding year. This increase was entirely under the head of primary vaccination. Of re-vaccination, there was a decrease of 6,142 cases. In Rangoon town the decrease in the number of primary vaccination and re-vaccination operations together, amounted to 14,754 cases. Taken in connection with the fact that upwards of a third of the total number of small-pox deaths recorded in Lower Burma took place in Rangoon town alone, this falling-off in the number of vaccine operations is suggestive. The cause assigned by the Health Officer to account for this decrease may be shortly restated. The President of the Municipal Committee in August last prohibited "the compulsory adult vaccination which "generally contributes by far the largest proportion of operations." As a result, practically no vaccinations were performed on adults for the remaining seven or eight months of the official vaccination year. The President's order was based on the death of a *mali* of the German club from tetanus following vaccination, and which was supposed to be a complication of the operation. The Health Officer, it is added, does not admit that "tetanus was due to vaccination." The sequel is thus described :—"The President's order has produced such a scare in the popular mind that, notwith-"standing all the efforts on the part of the vaccinators, no adult coolies, who keep constantly pouring "into Rangoon in large numbers, could be persuaded to submit to the operation." The consequences of the President's action will not be limited to the decrease of vaccination and the increase of small-pox in Rangoon. These unprotected adult coolies will prove a source of danger not only to the port in which they land, but to whichever part of Burma they migrate. Regarding the vaccination of infants, the Sanitary Commissioner considers the results to be so far satisfactory. The number vaccinated in excess of that of the preceding year was 22,753. But if the estimate that 127,561 children under one year were available for vaccination is approximately correct, and only 63,484 infants were successfully vaccinated, it follows that slightly more than half remained unprotected against small-pox. In both primary vaccination and in re-vaccination, the percentages of success were higher than during the preceding year, those of the former rising from 91·21 to 92·01, and those of the latter from 46·01 to 58·79. A separate account is given of vaccination in Upper Burma : this is inconvenient; and the Lieutenant-Governor directs that in future reports the two parts of the province should be treated together, and the statements concerning them should be amalgamated. The progress of vaccination in Upper Burma continues to be satisfactory. The total number of persons vaccinated rose from 115,703 in 1895–96 to 126,464 in the year under report; whilst in primary vaccination the percentage of successful cases was 93·34, and in re-vaccination 64·64, as compared with 92·67 in the former, and 66·65 in the latter during 1895–96.

7. The number of deaths from *Fever* is the highest ever recorded. This need not be taken to imply that the disease was unusually prevalent and fatal, but merely that the registration of deaths from this, the principal cause, as from the other causes of mortality is year by year becoming more complete. The scheme for the sale of quinine, which has been working for rather more than a year, has not, it is stated, quite achieved the success that was hoped for. Suggestions are offered with the object of diffusing more widely a knowledge of the value of quinine, and of how and where the drug may be obtained, in the hope that its purchase may thereby be stimulated.

8. The Sanitary Commissioner makes some interesting remarks regarding the influence of water-supply on the prevalence of diarrhœa and dysentery. After giving a list of towns with the highest ratios of deaths from these diseases, he adds :—"Some of these towns get their water-supply from "rivers, some partly from rivers partly from wells, and some have to rely on wells entirely. No "relation between these various sources of supply and the incidence of bowel complaints is "discernible, nor can any be traced in the sanitary defects or in meteorology."

9. *Sanitary works.*—No Sanitary work of importance was undertaken during the year, although some preliminary surveys and experiments were carried out with a view of arriving at a decision

regarding the kind of schemes most suitable for adoption. In Burma, as in every other province, the want of funds stands in the way of sanitary improvement. "Government is unable to lend money " this year to municipalities except for plague suppression and famine relief purposes." The account given of the sources from which Rangoon is supplied with water, if not overdrawn, suggests urgent need for their protection against pollution. "The water from the lakes has been unfavourably " reported on by the Chemical Examiner and is not passed through any filter beds." Further, it is stated that " on the edge of Victoria Lake there is a water-closet, and about 200 feet further there are " three villages. About 300 feet from the Royal Lake's high-water mark are situated residences " with water-closets &c."

10. Sanitary inspection registers have been introduced into nearly all headquarters of townships and subdivisions; but it does not appear that much has yet been done towards the filling up of these registers with such remarks on the sanitary condition of the towns and villages in which they are kept as might serve as a useful permanent record. The extension of this system of sanitary record to the country generally, although certainly desirable, must, from the vastness of the area to be dealt with, and the limited number of agents possessed of the knowledge needful to enable them to make a useful inspection and to record its results, be a question of time. "The labours of the Sanitary " Board appointed in 1888 continued to be barren, but the appointment of a Sanitary Engineer for " the province in November next will doubtless afford useful material for their deliberations." Such is the verdict passed on the Board by the Lieutenant-Governor.

11. Briefly, strenuous efforts are being made, and with marked success, to improve the registration of vital statistics. The Lieutenant-Governor impresses on Deputy Commissioners the importance of their earnest co-operation in the endeavour to accelerate this improvement. The recorded birth-rate was 32·27, and the recorded death-rate 23·63 per mille for the province; and, although these rates are undoubtedly still much below the reality, they indicate a great improvement in registration as compared with the figures for 1872, when they were respectively 17·79 and 12·48. Cholera was not unusually fatal. It would have been useful if the Sanitary Commissioner had given some account of the conditions which seemed to influence the progress of the disease, and especially some account of the water-supply in the affected areas; also, if he had stated whether any measures were adopted with the object of cutting short outbreaks of the disease and if these measures proved successful. Small-pox did not prevail in severe epidemic form. A large proportion of the deaths occurred in Rangoon town—a result attributed by the Health officer to the action of the President of the Municipal Committee in prohibiting the compulsory vaccination of adults, in consequence of a native having died of tetanus following vaccination. Except in Rangoon, vaccination made satisfactory progress. The mortality ascribed to fever was the highest hitherto recorded in the province, a result probably due to improved registration rather than to greater prevalence of the disease. No sanitary works of importance were undertaken during the year, although preliminary surveys and experiments were carried on with a view to works being put in hand so soon as a sufficiency of funds should become available.

12th October, 1898.

No. 6.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Central Provinces for 1896.

In his remarks on the Annual Sanitary Report for 1895, the Chief Commissioner expressed a fear that the year 1896, like its predecessor, would also show a falling off in births, "the series of bad " harvests not having yet been broken by a cycle of prosperity." This fear was fully realised. The year under notice proved to be one of remarkably abnormal conditions. Owing to the premature cessation of the rains in 1895, succeeded by a rainless cold and hot weather up to the setting in of the monsoon, the spring crops failed in all except a few districts. It was hoped that the monsoon of 1896, when it did set in, would at length put an end to the hard times and privation from which the people had suffered during the preceding years of bad harvests. Until the end of August the monsoon was favourable and everything gave promise of an abundant autumn crop; but again were these hopes disappointed—the rains ceased early in September, and under the influence of the succeeding heat and drought this promise of relief faded away. Prices rose to such a height as to be beyond the means of people already reduced to poverty by a continued succession of crop failures, and before the end of the year the greater part of the Provinces was in the grip of a calamitous famine.

2. *Vital Statistics.*—The *birth-rate*, which in 1895 was the lowest recorded within the previous 15 years, further decreased during the year under review and stood at 31·72 per mille of population, as compared with a decennial mean of 40·66 for the period 1882–91. Up to the year 1894 the birth-rate was fairly constant, and fell little below what may be assumed to be its normal ratio of somewhat over 40 per thousand of population. That the diminished prosperity accompanying or following a succession of bad harvests should be reflected in diminished fecundity was no more than was to be expected. In one only of the 18 districts of the Central Provinces did the number of births exceed the number of deaths. This district, Sambalpur, is practically outside the area affected by scarcity, a fact which tends to confirm the conclusion that the decrease of the number of births was mainly, if not entirely, due to the failure of the crops in the rest of the Provinces, or to the conditions of privation and distress resulting from such failure.

3. As the birth-rate diminished under the adverse influences of scarcity in 1895 and the first months of 1896, so under the operation of the same influences the *death-rate* greatly increased. The deaths exceeded in number those of the previous year by no fewer than 119,332; and the ratio per mille of population rose from 36·75 to 49·31. This is the highest death-rate recorded during the preceding decennium. In 15 of the total number of 232 registration circles the death-rate exceeded 90 per thousand of population. The highest ratio recorded was 172·21 in the Damoh circle of the Damoh district.

4. "It is remarkable," writes the Chief Commissioner, "how closely the maximum falling-off in "the birth-rate corresponds with the area of maximum harvest failure and consequent distress. It "would seem that a markedly short birth-rate may be accepted as almost conclusive evidence of the "prevalence of pressure on the labouring population." The districts in which this decrease of the birth-rate was most marked are at the same time those in which the death-rate was above the provincial average of 49·31; they are also the districts in which "distress culminating towards the "end of the year in acute famine was prevalent." On the other hand, the only district in which the birth and death-rates were practically normal was that of Sambalpur; and in this, distress due to scarcity did not exist. Whatever other conditions therefore may have been concerned in bringing about increase of the death-rate and diminution of the birth-rate during 1896, it may be accepted as certain that none was equal in importance to privation and distress due to scarcity of food.

5. In accordance with past experience, the incidence of a scarcity and famine was most severely felt by the feeblest part of the population. Children under one year of age died at the rate of 318·14 per mille of the number born in 1896, as compared with a rate during the preceding year of 259·89. "The increase in the death-rate among infants," writes the Sanitary Commissioner, "corresponds "with a decrease in the number of births registered due to the effects of extreme privation retarding "the natural growth of the population." The death-rate amongst the very old was at the same time high.

6. Although the mortality was greatest, as usual, in the months succeeding the rains, each month of the year "was characterised by a death-roll higher than in the previous year." The high death-rates of August, September, and October were due chiefly to the prevalence of malarial diseases acting on constitutions enfeebled by privation.

7. A comparison of them shows that, taken for the whole Central Provinces, there is no very marked difference between the vital statistics for the rural and those for the urban population. The death-rate in towns in which registration was compulsory exceeded by 1·46 per thousand of population the rural death-rate; and the urban was less than the rural birth-rate by 1·07. The enormous death-rates of some of the towns, such as Damoh, are said to have been due in part to the influx from bordering Native States of "emaciated and moribund immigrants."

8. The table given at the foot of page 5 of the report compares the ratio of deaths in accordance with class. The remarkable difference between the death-rates amongst Hindus and Mahomadans, and those recorded for "other classes," is not explained by the Sanitary Commissioner; but in his review of the report the Chief Commissioner writes:—"It is a noticeable feature of the mortality of "the year that one-quarter of the deaths registered, or 122,662, were of 'other classes,' under which "denomination the aboriginal and jungle races are chiefly included. The per millage rate to the total "of these classes was 87·34 against 42·69 Hindus and 43·12 Mussalmans." It is the general experience that owing to their shy, suspicious character, and the natural difficulties of the hilly and forest tracts in which they live, these tribes cannot be so effectually relieved during times of scarcity as the more civilized inhabitants of the plains. Rather than do any regular work, or accept aid in the form of grain or even of money, many of them prefer to subsist on forest roots and fruits until they have become so reduced that, when at length provided with a sufficiency of wholesome food, their restoration to health is found to be hopeless. Needless to add, the mortality amongst such tribes during the prevalence of scarcity or famine is sure to be great.

9. *Chief Diseases.*—Famine is usually, although not invariably, accompanied or followed by pestilence. During 1896, scarcity deepening into actual famine reduced the resisting powers of the people, and thus prepared the way for the destructive effects of disease. To *cholera* alone 52,985 deaths, equal to a ratio of 5·58 per mille of population, are attributed. Only once during the previous ten-year period has this number been nearly approached. The disease prevailed in every one of the 18 districts, but as a rule proved most fatal in the districts in which distress arising from scarcity was most acute. In the northern districts of the Provinces it was especially prevalent and fatal. In one of these, Mandla, the ratio rose to 15·75 per mille. In one of the north eastern districts, Bilaspur, it was 10·99. On the other hand, in Sambalpur, in which there was no scarcity, the ratio was only 1·73. In four other districts the ratio was under 2 per thousand of population. In all of these four there was failure of crops, and greater or less scarcity. It thus appears that, although the prevalence of cholera bears some proportion to the degree of distress in most of the districts, this proportion was not a constant one. From a minimum of 29 deaths in January, the number increased month by month until the maximum of 14,000 was reached in June. From the latter month the number of deaths decreased, until in November they had fallen to 143. "The exceedingly dry and hot spring "and summer was the season of the greatest prevalence of cholera, which reached its maximum in "April (8,407 deaths), May (12,935), and June (14,000). The scanty and foul water-supply, which "was the natural result of the drought, may reasonably be supposed to be also the main cause of the "cholera, which, besides the above districts (those of the Jabalpur division), was particularly "prevalent in Bilaspur and Raipur districts, which rely for their water-supply upon tanks formed by "impounding the surface drainage."

10. Consequent upon a sudden and severe outbreak of cholera which occurred amongst a number of officers who had dined together at Saugor on the evening of the 13th July, Mr. Hankin, the Bacteriologist to the Government of the North-Western and Central Provinces, accompanied by the

Sanitary Commissioner of the Central Provinces, made a bacteriological inquiry into the cause of the disease. "After inquiry, Mr. Hankin was of opinion that the fish caught in the Saugor Lake and "brought alive into the mess had been the means of introducing the cholera microbe into the mess." A subsequent inquiry, made about the 14th of August, led to the adoption of the theory that the dish-cloths used by the cooks had become infected with the cholera microbe whilst drying on the banks of a cholera-infected stream, and had, in turn, infected the food in the cook-house. An account of the outbreak and of the bacteriological inquiry will be found at pp. 140–143 of the Annual Report of the Sanitary Commissioner with the Government of India for 1896. The report concludes :— "However much we may admire the ingenuity of this hypothesis, it must be admitted that there are "few facts in its support." It will be observed that the inquiry regarding the causation of the disease is based on the assumption that the cholera microbe is the cause of cholera. To quote again from the Report of the Sanitary Commissioner with the Government of India :—"The statement that "cholera is caused by a particular vibrio must remain an assumption until the circumstances under "which that vibrio is potent to cause cholera has been discovered."

11. *Small-pox*, like other diseases, was unusually prevalent during the year. The deaths caused by it numbered 7,747, as compared with the mean for the previous quinquennial period of 2,298. The increase of mortality affected every district of the Provinces without exception ; but the districts which suffered most were not, as in the case of cholera, chiefly those in which privation was most severe. As usual, the disease prevailed with greatest virulence during the hot weather, and began to decrease in severity after the setting-in of the monsoon. By far the larger proportion of deaths occurred amongst infants under one year of age and children between one and 12 ; only 2,268 occurred amongst the population of ages exceeding 12 years. The decrease in the number of persons vaccinated during 1895–96 continued through the vaccination year 1896–97. The same causes to which the decrease was due in the former year were in operation during the latter. Whilst, under the adverse influence of distress arising from crop failure, the birth-rate fell from its normal of upwards of 40 per thousand of population to 31·72, the death-rate amongst children under one year of age rose to 318 against a normal of 260. In addition, vaccinators were in several districts withdrawn from their proper duties for work in connection with famine. Under these circumstances, it is no matter for surprise to find vaccination operations, which numbered 371,438 in 1895–96, decreasing to 327,457 in the year under report. The percentage of successful cases was about the same in both years. Of the children born during the vaccination year, 26,826 are calculated to have remained unvaccinated, as compared with 21,328 in the preceding year. Of revaccinations there was a large decrease, "which may be in part due to the orders issued on the subject. Vaccinators are frequently "tempted to perform revaccination more frequently than necessary with a view to supplement their "record when the number of primary operations falls short of the average. This practice has been "discouraged of late years." The Sanitary Commissioner states that arm-to-arm vaccination is now practised in very few places, animal being substituted for human lymph. The cost of supplying calf lymph during the year was only Rs. 211. 0. 9.

12. *Fevers* were excessively prevalent : the ratio of deaths from them rose to 29·55, as compared with a decennial average of 20·98. The disease was of the ordinary malarial type, and is said to have impartially attacked all classes, the well-to-do alike with those reduced by privation. The months during which it was most fatal would seem to confirm the belief in its malarial origin : it prevailed with greatest severity during the last five months of the year. At the same time its effects were most fatal in Damoh and Saugor, two of the districts which suffered most from scarcity during a series of seasons leading up to 1896, when it culminated in calamitous famine ; whilst its effects were least severe by far in Sambalpur, a district which did not in 1896, nor previously, suffer from scarcity. It is said that the Nimar district was likewise exempt from famine ; and its high fever death-rate of 46·26 is attributed in part to the influx of starved wanderers from other districts and provinces. The Sanitary Commissioner states with regard to Nimar that "the abrupt cessation of the monsoon at the "end of August proved disastrous to the crops," and adds, "there was little evidence of want or "scarcity among the people of the district generally, but the existence of famine and high prices "elsewhere caused a large influx of starved wanderers from other districts and provinces, and "accentuated distress among the artisan and weaving classes."

13. As might have been expected, *bowel-complaints* were unusually prevalent and fatal. The ratio of deaths caused by them increased from a decennial mean of 2·21 to 3·14. Their incidence was heaviest in the nothern districts ; in Jabalpur they caused a ratio of 9·79 deaths per thousand, in Damoh of 9·36, and in Mandla of 7·68. Their excessive prevalence in these districts was doubtless connected with the condition of distress from which the people of these districts were suffering. They belong to the class of so-called famine diseases, and, seeing that they are generally due to unsuitable or unwholesome food, their prevalence may be taken to imply a deficiency of suitable or wholesome food. There is no doubt that in jungle and hilly tracts the people are driven to subsist to a large extent during times of scarcity on jungle roots and fruits ; and that as a consequence of this dietary they suffer from and succumb to affections of the bowels.

14. The high death-rates recorded in some towns, such as Damoh, Jabalpur, and Murwara, were due, writes the Chief Commissioner, "to the existence in these towns of poor-houses where destitute "strangers were taken in, or the distribution of alms by private charity, which brought a large "number of beggars to centres where it was carried on."

15. *Sanitary Works.*—The most important of these were schemes for supplying water to certain municipalities. The Khandwa water-works were so nearly completed by the end of the year that it was possible to open them early in 1897. Progress, it is stated, is also being made with the works at Wardha, and a final estimate has been prepared for Bhandara. But during a year when the pressure of scarcity diverted the energies of the Public Works Establishments to famine relief, the prosecution of schemes of sanitary improvement had to remain more or less in abeyance for want of the establishment required to superintend their execution, and of the funds needful to carry them out. As the Chief Commissioner says :—"The scarcity and the subsequent famine greatly interfered with

"the active prosecution of sanitary reform which must wait for the setting-in of better times." The preparation of sanitary maps of districts continued in progress. The maps of two districts were received during the year, making a total of 12 now ready, and leaving only six more to complete the full number for the province. The Village Inspection Note Books prescribed by the Government of India have been introduced into selected villages in each district; but "owing to the unusual press of work in connection with famine and plague, Civil Surgeons devoted little time to village inspection." An examination of the list given on pages 52–53 of the report shows that the Civil Surgeons of the large stations of Jabalpur and Nagpur made no inspection of villages during the year; and that in the district of Hoshungabad only one village was inspected.

16. Briefly summed up: the year 1896 proved to be the worst of a series of seasons of bad harvests. The rains which for a time gave promise of being satisfactory, suddenly ceased about the end of August. Their cessation was followed by excessive heat and drought, which speedily withered up the crops and left the country in the grip of famine. The birth-rate was the lowest and the death-rate the highest ever recorded in the Central Provinces. The hard times and privation of the preceding years reduced the vitality of the people, lessening their fecundity, and rendering them more susceptible to the destructive effects of the diseases which usually accompany famine. As compared with the preceding year, the number of births decreased by 16,005, whilst the number of deaths increased by no fewer than 119,332. Cholera prevailed in every district, and carried off 52,982 people. Fevers and bowel complaints were unusually fatal. The sum of sanitary improvement in such a year could not fail to be small. The energies of the staff of every Department were fully occupied in relieving distress; whilst all available funds were required for providing the means for affording such relief. The year, in short, was from a health point of view, as probably from every other, the most calamitous which has hitherto befallen the Central Provinces.

No. 7.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Assam for 1896.

If an estimate of the state of the public health were deduced from the provincial vital statistics alone, it might be concluded that the year 1896 was the most unhealthy on record. In no previous year were so many deaths registered. The death-rate rose to a ratio of 36·33 per thousand of population and was in excess of the birth-rate by 2·64. We do not gather from the report that the meteorological conditions, or the high prices of food-grains were sufficient of themselves to account for this unusually high ratio of mortality. The information regarding the weather and prices is somewhat meagre and does not refer to the province as a whole, but is limited to three of the nine districts. In all of these three districts the rainfall was below, and in the case of one of them much below, the average; whilst in two of them the mean temperature was above, and in the third slightly below, the average. In two of the three prices were slightly, and in the third greatly, above normal. This dearness of food would doubtless unfavourably affect the public health by lowering the vital stamina, and consequently the resistance of the population to disease. But the strenuous endeavour of the Administration to improve registration was probably the chief cause which contributed to raise the death-rate. The effect of such improvement would be to lessen the number of deaths omitted from the registers, and so to bring about an apparent rather than an actual increase in the year's ratio of mortality.

2. If the registration of *births* is carried out with the same degree of accuracy as the registration of deaths, the population of Assam, instead of increasing, shows a tendency rather to decrease. Whilst the birth-rate for 1896 was only 33·69, and for the preceding year 31·00, the corresponding death-rates for the two years were respectively 36·33 and 33·72. For the five-year period preceding 1896 the ratios of births and deaths almost balanced each other, the birth ratio having been 30·38 and the death ratio 30·17. It is probable, however, that in Assam, as in other provinces of India, the number of births which are omitted from the registers exceeds the number of deaths omitted.

3. The Sanitary Commissioner compares, as he did last year, the death-rate recorded in Assam with the death-rates recorded in other Indian Provinces. From this comparison it appears that the Assam rate is only exceeded by the rate for the Central Provinces. In these latter, under pressure of scarcity, the people suffered greatly and the mortality was excessive. The two chief agencies employed in Assam for recording births and deaths were, as hitherto, the village watchmen, who are paid, and the village headmen, who are unpaid. The former are employed in the Surma, and the latter in the Brahmaputra Valley. Their comparative efficiency as registrars may to some extent be judged of by the ratios of birth and deaths recorded for the districts in these two valleys. Where, as in the Surma Valley, vital statistics are collected by paid watchmen, the ratio of births is 37·32 and of deaths 35·43; whilst in the Brahmaputra Valley the corresponding ratios calculated on the numbers of births and deaths recorded by unpaid village headmen are 30·13 and 37·39. The Sanitary Commissioner says:—"The monthly returns of vital statistics were carefully scrutinised in this Office, "and, when the numbers for any registration circle were obviously inaccurate, the notice of Deputy "Commissioners was called to the matter, with the request that they would cause inquiries to be "made with a view to include in the registers any vital occurrences which; by oversight, had not "been entered in the registers." Such a procedure, if generally followed by Sanitary Commissioners,

would render the publication of the full details given in Forms I. and II. appended to the Annual Report superfluous. The abridgment of these two forms, now sanctioned by the Government of India, could then be carried into effect without any fear of detracting from their usefulness, and with the result of greatly lessening the time and labour required for their preparation and publication.

4. Although progress in promoting accuracy of registration is being made, much remains to be done before the ratios of births and deaths can come to closely approximate the estimated ratios of 48 births and 42 deaths per thousand of the population. Dr. Stephen has given, in paragraphs 7 and 8 of his report, tables which record the number of married women between the ages of 15 and 39 in the *sadr* and sub-divisional towns of Assam, and the probable number of births calculated at the rate of 320 births of children per thousand of these women. The number of children born according to this calculation would give, in *sadr* towns, a birth-rate, per thousand of population, of 43·40; whilst the number actually registered gives a birth-rate of only 26·07. In sub-divisional towns the birth-rate similarly calculated would be 40·11, as compared with 30·40 calculated on the number of births actually registered. This test effectually disposes of the explanation so frequently offered to account for the low birth-rates recorded in towns—the preponderance in the number of males over the number of females in the population. Another point illustrated by the vital statistics of Assam, is the tendency which the number of males born has to approximate to the number of females born in proportion to the accuracy of the registration. Where registration is more carefully carried out by the paid village watchmen in the Surma Valley, there are, on the average, 106 male to every 100 female births recorded; where registration is less carefully carried out by unpaid village headmen in the Brahmaputra Valley, the average is 108 male to every 100 female births. Punishments are freely inflicted on watchmen and headmen who fail to report births and deaths. In a single district 519 of the former were punished, and in another district 120 of the latter. The details given by the Sanitary Commissioner in the 19th paragraph of his report show that the testing of the registers of vital statistics by Inspectors of Vaccination was, on the whole, carried out in a perfunctory manner. Civil Surgeons might be held responsible for seeing that the Vaccination Staff do not neglect this important part of their duties.

5. *Chief Diseases.*—Under the head of *cholera* 17,042 deaths were recorded, a number considerably less than that recorded for the previous year, and 2,193 less than the average of the five years 1890–94. In most provinces of India the months of least cholera mortality are the coldest, the first and last months of the year. In the districts of the Surma Valley of Assam, November, December, and January were the months of greatest, and June, July, and August the months of least, cholera mortality. In the districts of the Brahmaputra Valley there were two periods of maximum prevalence, and the same was the case in 1895 and in the three-year period 1892–94. The former of these periods included the months of April, May, and June; and the latter, November and December. The periods of minimum prevalence were also two: the first in January and February, and the second in August and September. The obscure nature of the conditions which determine the degree of severity with which cholera may prevail in two different localities is well shown in the report. "In 1895 cholera was most prevalent in the Kamrup, and least prevalent " in the Nowgong District. In the year under review, the disease was most prevalent in the Nowgong " and least prevalent in the Kamrup District." Tables 16 and 17 of the report would seem to suggest some connection between cholera prevalence and rainfall. The months of least rainfall, judging from the figures in the table, seem to be those of highest cholera mortality, and *vice versâ*. It might have been useful had the mean temperature of each month been shown along with the rainfall and ratio of cholera mortality of that month. It is probable that temperature decreased with rainfall and increased with the absence of rainfall. " These climatic conditions," writes Dr. Stephen, " are, however, merely " predisposing causes, and whatever the exciting cause of the disease may be, experience has shown " that it may be rendered inoperative by removing sanitary defects." It is a relief to find some one with the courage to set aside theories and assumptions regarding the causation of cholera, and who confines his remarks to what is known and practicable. He adds :—" Of the insanitary conditions " likely to produce cholera, impure water-supply is the principal, and cholera will be prevalent in this " province as long as the water-supply is liable to contamination by human impurities." To secure a water-supply which shall not be " liable to contamination," and to convert the people from their preference for water from tanks and rivers which are, and probably ever will be, " liable to " contamination," and which they have been accustomed to use from time immemorial, is a task which may exceed the power of the State to accomplish; but there is hope that the people themselves may come to appreciate the advantages of a pure water-supply, and so to give up using water from sources obviously liable to pollution. Yet, even when a pure water-supply has been provided, security against cholera will not necessarily be complete. " The water-supply in tea gardens is, for the most part, very " well protected, whereas in villages it is liable to all kinds of pollution." Notwithstanding this, the cholera death-rate among tea-garden coolies was 4·64 per 1,000, and that among the general population, excluding tea-garden coolies, only 3·30 per 1,000. The excessive mortality from cholera among tea-garden coolies has long engaged the attention of the Administration; and an experienced medical officer was deputed to inquire into its causes and to suggest remedies. This officer, after the completion of his inquiries, brought to notice many defects observed by him at the central coolie depôts, and during the journey by train and steamer, and made valuable practical recommendations with the view of remedying these defects; but the Sanitary Commissioner thinks that, so long as the coolies travel under existing conditions, cholera is liable to occur among them during the time they are on board the river steamers " however carefully the regulations may be carried out." He is, therefore, induced again to recommend " that arrangements be made for having all tea-garden coolies protected by " M. Haffkine's anti-cholera inoculation, before they are put on board the river steamers." Whether this recommendation, if carried into effect, would be successful in protecting the coolies from cholera during their transit to the tea gardens is a question which experience alone can decide.

6. *Small-pox and Vaccination.*—The deaths from small-pox numbered 5,444, and exceeded the number of deaths from this disease in the preceding year and the average number in the five-year period 1890–94. The ratio of deaths per 1,000 of population was 1·09; but in some districts was

much greater, reaching in Lakhimpur 4·16. The disease is shown to have been imported into parts of the province from Calcutta; but such importation would not have lighted up epidemics had the people amongst whom it was introduced been effectually protected by vaccination. Judging from the returns of vaccination for 1896-97, the protection of the population of the province against small-pox might be supposed to be great. No less a ratio than 45·71 per thousand of the population is stated to have been successfully vaccinated during the year. This ratio largely exceeds the birth-rate; but if the number of successful primary vaccinations of children under one year of age is compared with the number of births registered in 1896, it will be seen that there were only 45,865 of the former to 169,172 of the latter. Deducting from the latter figures the 36,353 deaths of children under one year of age, there would remain available for vaccination 132,819. Deducting again from this last number the number successfully vaccinated, there would remain 86,944 unprotected children. It will be evident, therefore, that vaccination, although making good progress in Assam, cannot yet be expected to control small-pox epidemics. To quote the Sanitary Commissioner's remarks :—" From the diagram " it appears that the death-rate from small-pox was highest in the Lakhimpur District, in which the " largest proportion of the inhabitants was successfully vaccinated during the last seven years, and " that the small-pox death-rate was also comparatively very high in the Sibsagar District, in which " the next highest proportion of inhabitants was protected." It is an unfavourable feature of the returns that there was some falling-off in the number of infants vaccinated. The number vaccinated in 1896–97 was 45,865, as compared with 47,176 in 1895. The percentage of successful operations recorded in Assam has attracted the notice of his Excellency in Council, who views some of the figures with grave doubt. To be asked to believe that of the 12,970 vaccine operations performed in a single district every one was successful, is a severe strain upon the credulity of anyone who has seen much of vaccination in India. It is suggested by the Government of India that the Sanitary Commissioner should himself verify a considerable number of the cases in the district of Nowgang. Calf vaccine lymph has largely superseded the use of humanised lymph, although arm-to-arm vaccination was still practised in two districts. The mortality among the calves bought for the supply of lymph seems to have been excessive. Of the 435 calves vaccinated during the year, " 20 died " before the vesicles were developed and 75 after lymph had been taken from them." In a country in which the cow is venerated, the deaths of so many calves in connection with the supply of vaccine lymph might possibly have the effect of increasing the caste prejudices of the vaccinators, already said to be strong, and thereby of making it difficult to procure a number of calves sufficient for the supply of vaccine lymph for the province.

7. *Fevers* are credited with having caused 101,347 deaths, or a ratio of 20·18 per mille of population. This ratio is considerably higher than that recorded for the preceding year, and very much higher than the average ratio for the five-year period 1890–94. This latter was only 16·18 per thousand of population. The steady improvement shown to be taking place in registration, rather than increase of mortality from fevers, is probably the main cause of this increase in the death-rate attributed to fevers. In the total number of deaths recorded as due to fevers are included deaths from malarial fevers, from kala-azar, and all other diseases in which rise of temperature is a prominent symptom. The differentiation of deaths due to kala-azar from those due to other fevers is probably difficult, and in some cases impossible. The number of deaths assigned to kala-azar in the returns is 15,894, and practically all of these were recorded in three of the nine districts of the province. The conclusion arrived at by Dr. Rogers, who was deputed to make inquiries regarding the origin and causation of this disease, differs from that which Dr. Giles had previously come to. Dr. Rogers is of opinion that kala-azar is an intense form of malarial fever, and that it is communicable. In our remarks on this disease in our Memorandum for 1895, we briefly stated the reasons which seemed to be opposed to the acceptance of the views held by Dr. Giles that kala-azar was due to the presence in the intestines of the parasite *Anchylostomum duodenale*. During the year increased facilities were provided for the purchase of quinine. Hitherto the people have perhaps not availed themselves of the facilities promised for them to the degree which was anticipated; but the most the State can be expected to do is to teach them the use of the drug, and to place it within their reach for purchase.

8. *Sanitary Works.*—In consequence of the want of funds, " very few important sanitary works " were put in hand or carried out during the year." Shillong and Gauhati are the only towns in which water-supply works have been constructed, and, comparing their death-rates before and after the introduction of these water-supply works, it appears that whilst the death-rates recorded during the five-year period preceding the opening of the works were 28·55 for Gauhati and 14·14 for Shillong, these rates had risen in the year under report to 36·48 and 14·32 in these towns respectively. These figures need not, however, be taken seriously. The increase is more likely to be the result of improved registration than of greater mortality. No very marked progress in the execution of important sanitary works need be looked for whilst the combined incomes of all the " municipalities, " stations, unions, and towns in the province " does not much exceed two and a half lakhs of rupees per annum; but the Sanitary Commissioner shows that " considerable attention continues to be " given to drainage, water-supply, and conservancy arrangements; and that nearly 50 per cent. of " the limited funds available were spent on ' sanitation proper.' "

9. Briefly, the year does not seem to have been an unusually unhealthy one, notwithstanding that the death-rate was the highest hitherto recorded. The improvement in the registration of vital statistics is probably the chief, if not the only, cause of the increase in the recorded number of deaths. Fewer births than deaths were registered, a result no doubt in part due to the well-known fact that fewer deaths than births escape registration. The number of deaths attributed to cholera was less than the number due to it in the preceding year, as well as less than the average in the previous five-year period. Small-pox, on the other hand, was more fatal than in the preceding years. Vaccination makes progress; but an unfavourable feature of the season's returns is the decrease in the number of infants vaccinated. The number of children under one year of age remaining unprotected against small-pox is great, and constitutes a constant source of danger when small-pox infection finds entrance into the province. Animal vaccine lymph is being substituted for humanized lymph throughout the province. We have noticed the excessive mortality amongst

the calves purchased for the supply of vaccine lymph—apprehending that this may possibly have an unfavourable influence in strengthening the prejudices already existing against calf-to-arm vaccination. Fevers are credited with having caused a considerably higher mortality during the past than during the previous year. Part, if not all, of this increase may be attributed to better registration. Few important sanitary works have been undertaken; but considerable attention was given to the water-supply, drainage, and conservancy of towns. Progress is necessarily restricted, owing to the limited amount of funds available.

12th October, 1898.

No. 8.

Memorandum by the Army Sanitary Commission on the Rajputana Sanitary, Vaccination, Dispensary, and Jail Report for 1896.

In the comparatively small portion of Rajputana known as Ajmere-Merwara, with its population of only somewhat over half a million, the rainfall was much above the average. In the rest of Rajputana, with its population of between 11 and 12 millions, the rainfall was either deficient or unseasonable for the crops. The early cessation of the rains was followed by extensive withering of crops and fodder as well as by scarcity of water. Prices were high in Ajmere-Merwara and still higher in many of the Native States. Distress resulted, and led to migration from some of the Native States of people with their cattle in quest of water and fodder. As in other parts of India in which the weather conditions of the year were more or less similar, this early cessation of the rains and the abnormal dryness of the subsequent months, although they resulted in scarcity of food and water, brought compensating benefits in lessened sickness and mortality from diseases due to malaria.

2. *Vital Statistics.*—The only returns which can be relied upon are those relating to the half million, or so, of people inhabiting the Ajmere Division. It is true that an attempt has been made to register births and deaths in 17 of the 21 Native States of Rajputana; but when we find one of these States recording a birth-rate per thousand of population of only 2·17 and a death-rate of only 3·17, it is evident that a good deal remains to be done before registration reaches the point when useful conclusions regarding the health conditions of the people can be drawn from the records of births and deaths. In the small population of Ajmere-Merwara for which reliable returns are available, the birth-rate fell from 35·29 in the preceding year to 32·77 in 1896. The Agent to the Governor-General, in his review of the Administrative Medical Officer's report, says:—"No satisfactory reason "has been given for the decrease in the birth-rate, and it points to defective registration." In our memorandum on the report of the previous year we wrote:—"The serious consequences of drought "have since become more fully manifest; and the more remote effects on fecundity and mortality "will doubtless be apparent in the statistics of the next and following years." As we had anticipated, there was in the year 1896 a decrease in the birth-rate, following, and due to, the poor crops and high prices of the preceding year. Registration was also unquestionably defective, but there is no evidence of its having been more defective than usual. Whilst the birth-rate decreased, the death-rate increased from 26·95 to 28·25 per thousand of population. It has already been stated that the mortality from fevers, bowel-complaints, and cholera showed a decrease; but this was more than counterbalanced by increased mortality from small-pox. The deaths among children under five years of age were excessive, accounting for no less than 55 per cent. of the total mortality of the year. As in other provinces of India, "the death-rates are generally more accurate than the birth-rates, "as it is less difficult to get deaths reported; the births of female children are specially suppressed, as "girls are still looked upon as a great discredit to parents and the household in general."

3. *Chief Diseases.*—Of *Cholera* there were only four sporadic cases in Ajmere-Merwara; but in several of the Native States the disease prevailed in epidemic form, 6,787 cases and 3,798 deaths having been reported. Much reliance cannot, however, be placed on these figures. By far the most severe outbreak occurred in Marwar, into which the disease is supposed to have been introduced by coolies from Bikanir. At Nawa, where 3,000 coolies were at work on the new salt pans in the Sambhar lake, there was a severe outbreak which was followed by the flight and dispersion of the coolies to their villages. But for the flight of the coolies "the mortality must have been much "greater, notwithstanding the disinfection of the wells by permanganate of potash and other sanitary "measures carried out to mitigate the virulence of the epidemic." The coolies of their own initiative adopted the most effectual method yet discovered of cutting short a cholera outbreak. In their flight, it is said, they disseminated the disease widely over Marwar.

4. The ratio of deaths due to *Fever* in Ajmere-Merwara was 17·34 per mille of population, as compared with 20·89, the mean of the previous five years. Contrary to the ordinary course of the disease, the highest mortality from it was recorded during the first, and not during the last quarter of the year, a result which may be attributed to the early cessation of the rains and abnormal dryness of the subsequent months. The sale of quinine at post offices was continued, and 36,618 doses were sold, as compared with only 34,782 during 1895. The increase in the sales would probably have been greater but for the diminished prevalence of malarial fever during the year. The continuance of the scheme for a further period has been sanctioned.

5. A severe epidemic of *Small-pox* accounted for 3,821 deaths in the Ajmere Division, equal to a ratio of 7·03 per thousand of population, as compared with a ratio of only 1·28 for the previous five years. If the best measure of the efficiency of vaccination is the degree of protection it affords

against small-pox, a high estimate cannot, judging from these figures, be placed on its efficiency in Ajmere-Merwara. The primary vaccinations increased from 15,583 in 1895–96 to 15,962 in 1896–97; whilst the percentage of successful cases increased from 96·24 to 96·82. Of children under one year of age, 11,128 were successfully vaccinated. The number of children born in 1896 having been 17,773, and the number who died under one year of age having been 4,624, there would remain available for vaccination 13,149. Consequently, the unvaccinated residuum would number 2,021. As usual, young children were the chief sufferers from small-pox. Of the total number of 3,821 deaths from this disease, 1,244 were those of infants under one year of age; whilst 2,458 were deaths of children under 12. In some places the mortality from small-pox was very high. In Goella, out of a population of 6,633, there were 297 deaths from this disease, giving a ratio of 44·78 per *mille* of population. In the Native States, with their population of between 11 and 12 millions, 4,021 deaths from small-pox were recorded. This probably is only equivalent to saying that registration in them is unreliable. In these States the numbers successfully vaccinated fell from 294,628 in 1895–96 to 269,300 in 1896–97. The success claimed in some States is phenomenal: in no fewer than 10 of the 21 the recorded percentage of successful cases in primary vaccination is 99 and upwards. Possibly, as in Bengal, some of the vaccinators are in the habit of omitting from their registers unsuccessful cases. However this may be, it is hard to believe that in a large proportion of these Native States nearly cent. per cent. of the operations prove successful.
